Abstract

The field of noble gases chemistry has witnessed amazing advances in the last decade with over 100 compounds reported including Xe oxides and Xe-Fe alloys stable at the pressure-temperature conditions of planetary interiors. The chemistry of Xe with planetary materials is nonetheless still mostly ignored, while Xe isotopes are used to trace a variety of key planetary processes from atmosphere formation to underground nuclear tests. It is indeed difficult to incorporate the possibility of Xe reactivity at depth in isotopic geochemical models without a precise knowledge of its chemical environment. The structure of Xe doped hydrous silica-rich melts is investigated by *in situ* high energy synchrotron X-ray diffraction using resistive heating diamond anvil cells. Obtained pair distribution functions reveal the oxidation of Xe between 0.2 GPa and 4 GPa at high T up to 1000 K. In addition to the usual interatomic distances, a contribution at 2.05 ± 0.05 Å is observed. This contribution is not observed in the undoped melt, and is interpreted as the Xe-O bond, with a coordination number of about 12 consistent

with Xe insertion in rings of the melt structure. Xe solubility measurements by electron microprobe and particle induced X-rays emission analysis confirm that Xe and Ar have similar solubility values in wt% in silicate melts. These values are nonetheless an order of magnitude higher than those theoretically calculated for Xe. The formation of Xe-O bonds explains the enhanced solubility of Xe in deep continental crust magmas, revealing a mechanism that could store Xe and fractionate its isotopes. Xenon is indeed atypical among noble gases, the atmosphere being notably depleted in elemental Xe, and very strongly depleted in Xe light isotopes. These observations are known as the ‘missing’ Xe paradox, and could be solved by the present findings.

1. Introduction

2 Noble gases are key tracers of Earth dynamics, and as such, Xe isotopes are impor-
3 tant markers of planetary and atmosphere formation (Staudacher and Allègre, 1982;
4 Pepin, 2006); they may also be used to track underground nuclear tests (Hourdin and
5 Issartel, 2000). In particular, the I-Pu-Xe system is used to date the formation of
6 the atmosphere (Ozima and Podosek, 1999; Avice and Marty, 2014) due to the very
7 short half-lives of ^{129}I (17 My) and ^{244}Pu (82 My). Degassing of the early Earth could
8 thus have massively contributed to the formation of the terrestrial atmosphere within
9 the first 100 Myr (Staudacher and Allègre, 1982). However, recent Monte Carlo sim-
10 ulations pointed out that given the uncertainties on Xe isotopic compositions, such a
11 catastrophic early degassing event could not be evidenced unambiguously, and that the
12 potential chemistry of Xe at depth must be solved first (Boehnke et al., 2015).

13 Xe abundances and isotopic ratios have been measured in a large variety of samples
14 (atmosphere, fluids, rocks) and from different geological contexts, from Archean rocks
15 (Pujol et al., 2011) to Martian meteorites (Gilmour et al., 1998). From these measure-
16 ments, it was pointed out as early as 1970 that Xe is missing from the atmosphere of
17 the Earth and Mars (Anders and Owen, 1977), a depletion relative to chondritic pat-
18 terns of up to 90% (Ozima and Podosek, 1999) and known as the ‘missing Xe’ problem.
19 Atmospheric Xe is besides strongly depleted in light isotopes (Krummenacher et al.,
20 1962), a depletion that could be even larger if the primordial Earth composition – from
21 which the present-day atmosphere is derived by mass-fractionation processes – is the
22 U-Xe component instead of a solar wind or Q-planetary component (Marty et al., 2017).
23 First high precision measurements of non-radiogenic Xe isotopes (Caffee et al., 1999)
24 and their correlation with $^{129}\text{Xe}/^{130}\text{Xe}$ ratio showed that the atmosphere was degassed
25 very early after minor iodine decay in the mantle, and then underwent mass fractiona-
26 tion. Three types of scenarios have been proposed to solve the missing Xe problem. (1)
27 Xe may have escaped from the atmosphere, possibly after ionization (Avice and Marty,
28 2014), (2) Xe may be hidden at depth in the core (Lee and Steinle-Neumann, 2006;
29 Zhu et al., 2014), (3) Xe may have simply not been accreted on the planet (Dauphas,
30 2003). The fact that Earth and Mars atmospheres are similarly depleted in light Xe
31 isotopes (Swindle et al., 1986) nevertheless points out to a phenomenon that does not
32 depend on the mass of the planet such as hydrodynamic escape or trapping in the deep
33 reservoirs unique to the Earth, i.e. lower mantle and core. Besides, core formation
34 (Kleine et al., 2002) was likely completed by the time Xe was lost around 110 My

35 (Ozima and Podosek, 1999). Discovery of Archean rocks with Xe isotopic composition
36 falling between primitive chondrites and present Earth atmosphere (Pujol et al., 2011)
37 indicates a storage and fractionation of Xe throughout the Archean that could even
38 continue nowadays through subduction process. Geochemical tracing of Xe recycling in
39 the mantle (Trieloff and Kunz, 2005; Holland and Ballentine, 2006) points indeed to an
40 obvious link between Xe and water intake and release in subduction zones, resulting in
41 the storage of volatiles in the subcontinental lithosphere (Broadley et al., 2016). While
42 natural Xe concentrations are ~ 0.1 ppt in granites (Allègre et al., 1986) and ~ 0.05 ppt
43 in basalts (Ozima et al., 2002), they reach 0.2 ppb in deep sea siliceous fossils (Matsuda
44 and Matsubara, 1989) that may later enter subduction zones.

45 To understand Xe atypical behaviour, the mainstream approach has been to study
46 the relative stability of noble gases in melts relative to the major silicate minerals by
47 measuring partition coefficients. The results (Heber et al., 2007) span 4 orders of magni-
48 tude for Ar, and 7 for Xe, mostly due to different interpretations of where the noble gas
49 was incorporated, i.e. exclusively in bubble-free crystal zones or including sub-surface
50 and small bubbles as reflecting gas release upon quenching from high P - T conditions.
51 This highlights the extreme difficulty to probe the behaviour of volatile elements by an-
52 alyzing samples recovered at ambient conditions, either natural or synthetic. Besides,
53 despite its generally inert nature, Xe has been shown to react with crystalline planetary
54 oxides (Sanloup et al., 2005, 2011, 2013; Seoung et al., 2014; Crépisson et al., 2018) un-
55 der the high pressure (P)-temperature (T) conditions relevant of planetary interiors. Xe
56 oxides have been synthesized at ambient P and cryogenic T : XeO_3 , XeO_4 , Xe peroxides

57 (XeO_6^{4-} ion), XeO_2 (Brock and Schrobilgen, 2011), and lately Xe perovskites (Britvin
58 et al., 2016). On the high P side, Xe oxides have been predicted to be stable above
59 75 GPa (Zhu et al., 2013; Hermann and Schwerdtfeger, 2014), and observed above 77
60 GPa (Dewaele et al., 2016). Magmas being the most efficient transfer agents, the next
61 natural step was to determine Xe reactivity in silicate melts at depth.

62 The first and major objective here is to solve the retention mechanisms of Xe in
63 deep silicate melts by means of *in situ* high P - T X-ray diffraction experiments. While
64 X-ray absorption spectroscopy (XAS) is a classical method to probe the local envi-
65 ronment of elements in crystals, and used to evidence the Xe-O bond in high P Xe
66 oxides (Dewaele et al., 2016), it is difficult to use it for materials without appropriate
67 standards and with unknown structure, especially disordered materials such as mag-
68 mas. Instead, X-ray diffraction data are not model dependent. They are however
69 not chemically-selective and all ion-ion contributions must be solved. This implies to
70 work with simplified chemical compositions, such as haplogranitic magmas taken here
71 as analogues of continental crust melts, with only 5 elements (Si, Al, Na, K, and O),
72 and Si making 70 at% of the cations. X-ray diffraction is a well established technique
73 to probe the structural environment of major cations in silicate melts *in situ*, and the
74 recent study of Lu environment in compressed melts has demonstrated its potential to
75 probe the local environment of minor elements (de Grouchy et al., 2017). The second
76 objective is to measure the solubility of Xe in silica-rich melts at high P , current data
77 under high P conditions being limited to the tholeiitic composition (Schmidt and Kep-
78 pler, 2002), and discuss the structural data in the light of Xe solubility measurements

79 and theoretical estimates.

80 **2. Experimental Methods**

81 *2.1. Glass Synthesis*

82 The haplogranite (HPG) glass composition was chosen as a continental crust melt
83 analogue. The starting HPG glass was prepared by mixing reagent grade oxides (Al_2O_3 ,
84 SiO_2) and carbonates (Na_2CO_3 , K_2CO_3) powders. Powder was ground and decarbon-
85 ated by slow ramp heating from room temperature to 1473 K within 8 hours in a
86 platinum crucible, further fused at 1873 K in an atmospheric furnace for one hour, and
87 quenched in water. The obtained glass was crushed into a powder, and remelted twice
88 at 1873 K to ensure homogeneity. Hydration was done by high P - T synthesis at 2 GPa
89 and 1673 K using a piston-cylinder apparatus with a half-inch talc pyrex assembly, a
90 graphite heater, and dried MgO powder packed around the Pt capsule. Two hydration
91 levels were targeted, 5 wt% and 7 wt%. For that purpose, the glass was encapsulated
92 along with the approximate amount of distilled water in a platinum capsule weld shut
93 at both ends. Xenon doping was done subsequently by gas-loading (Boettcher et al.,
94 1989) another platinum capsule partially filled with the recovered hydrous HPG glasses,
95 and brought to 3.5 GPa and 1873 K for one hour, followed by rapid T quenching and
96 decompression at room T . The major part of the capsule material was used for X-ray
97 diffraction experiments, and a few glass pieces were spared for chemical analysis. The
98 HPG-7wt% H_2O composition was slightly contaminated upon retrieving the hydrated
99 glass from the first platinum capsule by the MgO P -medium packed around the capsule

100 (1.5 wt% MgO, cf Table 1).

101

102 *2.2. Recovered Sample Analysis*

103 Starting glasses and one sample (P5) were analyzed for major elements using a
104 CAMECA SX-FIVE electron microprobe analyzer (EMPA) at Camparis (UPMC, Paris),
105 using a defocused beam of 15 μm diameter and the following operating conditions: 1)
106 15 keV accelerating voltage, 6 nA beam current for Na, K, Al, Si, and 2) 15 keV and 100
107 nA for Xe. Calibration for Xe was established by measuring the counts for the neigh-
108 boring elements, I (CuI) and Cs (CsCl) following the procedure developed by Montana
109 et al. (1993). Hydrogen (i.e. water) and Xe contents were analyzed with the nuclear
110 microprobe of LEEL/LIMBE, CEA Saclay, France using ERDA (Elastic Recoil Detec-
111 tion Analysis) and PIXE (Particle Induced X rays Emission) respectively. For ERDA
112 (Bureau et al., 2009) we used a $4 \times 16 \mu\text{m}^2$ incident beam of ^4He at 3 MeV, mapped on
113 selected areas (up to $200 \times 200 \mu\text{m}^2$). For PIXE (Bureau et al., 2000, 2010), we used a
114 $3 \times 3 \mu\text{m}^2$ incident beam of protons at 2 MeV mapped on selected areas (up to 200×200
115 μm), and the Xe L X-ray line at 4.1 keV. Xe contents obtained by EMPA (Table 1) and
116 PIXE (Fig.1) compare well, except for one sample (P5) that we attribute to the sample
117 geometry as the sample surface could not be mirror polished, being embedded in the
118 epoxy while still in the rhenium gasket chamber. The PIXE measurements indicate
119 that the sample Xe content did not change during the course of the X-ray diffraction
120 experiment.

Table 1: Chemical composition in wt% obtained from EMPA except * from PIXE and ** from ERDA. Analyses are based on average of 10 data points, standard deviations are shown in brackets.

Oxide	plain glass	Xe-dopped glasses		Recovered sample P5

Figure 1: PIXE spectra of glasses and theoretical spectrum. Red line: starting glass (3.1 wt% Xe), green line: glass recovered from XRD run P5 (2.9 wt% Xe).

121 *2.3. X-ray Diffraction*

122 We collected *in situ* high energy synchrotron X-ray diffraction (XRD) data in re-
 123 sistive heating diamond anvil cells at the extreme conditions beamline P02.2, Petra
 124 III (DESY, Hamburg). High P - T conditions were generated by symmetric resistive-
 125 heating diamond-anvil cells (DAC) equipped with either 300 μm culet diamonds and
 126 70°-opening Boehler Almax seats (runs P5, P7, P11) or 800 μm culet diamonds and 80°-
 127 opening Boehler Almax seats (runs P3, P6). We used a high energy X-ray monochro-
 128 matic beam (60 keV) focused down to 4 μm × 6 μm to access a wide q -range of 15 \AA^{-1}
 129 (runs P5, P7, P11) to 16 \AA^{-1} (runs P3, P6), allowing high spatial resolution in di-
 130 rect space. While optimising the spatial resolution is always important in structural

131 studies, it is particularly crucial here to decipher the contribution of Xe, a minor ele-
132 ment. Heating was achieved by an internal resistive molybdenum-wire heater, and an
133 external heater set at 200°C around the DAC. The starting glass sample was loaded
134 in a 200 μm diameter hole drilled in a rhenium gasket. Pressure was measured from
135 the fluorescence of a ruby sphere (Mao et al., 1986) at ambient T , and from the unit
136 cell volume of platinum (Fei et al., 2004) at high T . Temperature was read by a type-
137 K thermocouple localized as close as possible to the sample chamber. *In situ* X-ray
138 diffraction data were collected for five different loadings (Table 2 and Fig.2), three on
139 the HPG-3wt%Xe-7wt%H₂O composition, one on the HPG-4wt%Xe-5wt%H₂O com-
140 position, and one on the undoped HPG-7wt%H₂O composition. The hydrous HPG
141 composition has a glass transition temperature low enough ~ 850 K (Dingwell, 1998)
142 to be achieved with a resistive heating furnace, and its high silica content (70 at%)
143 implies that the melt is highly polymerized with consequent high noble gases solubility
144 (Carroll and Stolper, 1993). The addition of water to the starting glass consequently
145 lowered the rate of recrystallization upon heating. Recrystallization occurred above the
146 glass transition T in only two runs, while the others remained in the amorphous state,
147 and were quenched as glasses. At each P - T point, 120 times 1 s diffraction patterns
148 were recorded on a Perkin-Elmer 2D detector, and summed. Diffraction patterns were
149 integrated using the Fit2D software (Hammersley et al., 1996). For each run, X-ray
150 diffraction patterns were collected at room conditions with an empty gasket inserted in
151 the DAC. The baseline of the recrystallized patterns (P7 and P11) was used to scale the
152 intensity of the empty background patterns. Obtained patterns were then subtracted

153 from the sample diffraction patterns to isolate the signal scattered from the melt.

Table 2: Summary of diamond-anvil cell runs.

Run	Starting composition	Quenched products
P3	HPG-7wt%H ₂ O	glass
P5	HPG-3wt%Xe-7wt%H ₂ O	glass
P6	HPG-3wt%Xe-7wt%H ₂ O	glass
P7	HPG-4wt%Xe-5wt%H ₂ O	crystals
P11	HPG-3wt%Xe-7wt%H ₂ O	crystals

154 3. Results

155 3.1. Overall structural description

156 To obtain a detailed description of Xe local environment in compressed silicate
157 melt, X-ray diffraction data were collected on both Xe-doped and plain samples as
158 X-ray diffraction is not chemically-selective. All ion-ion contributions must be solved,
159 which could be done in this study due to the chemical simplicity of the chosen magma
160 composition with only 5 elements (Si, Al, Na, K, and O), and Si making 70 at% of the
161 cations. X-ray diffraction intensity data are converted into the structure factor $S(q)$
162 (Fig.3A), where q is the scattering vector, using the Ashcroft-Langreth formalism. The
163 radial distribution function $g(r)$ (Fig.3B), that describes ion-ion contributions in real

Figure 2: Experimental P - T conditions. Circles: HPG-3wt%Xe-7wt%H₂O composition (white: P6, purple: P11, grey: P5); diamonds: HPG-4wt%Xe-5wt%H₂O composition (run P7), dark squares: plain hydrous HPG (P3).

164 space, is obtained by Fourier transforming of $S(q)$,

$$g(r) = \frac{1}{2\pi^2 r n} \int_0^\infty q S(q) \sin(qr) dq \quad (1)$$

165 where $n = \frac{\rho N_A}{M}$, M the mean atomic molar mass, and ρ the density calculated using
166 the volumetric properties determined for hydrous rhyolitic liquids (Malfait et al., 2014).

167 Whereas no changes were observed for the plain composition upon heating, an addi-
168 tional contribution is visible at 2.05 ± 0.05 Å above 573 K for the Xe-doped samples,

169 and vanishes upon quenching (Fig.3B). This additional contribution is observed for all
170 four experimental runs (Fig.1 to 3 in Supplementary Materials), and its intensity is

171 higher in run P7 for which the Xe content is higher (4 wt% *vs* 3 wt% for runs P5,
172 P6 and P11). Amongst the atoms present in our melt composition (i.e. Si, Al, Na,

173 K, O and H), only H and O are known to form compounds with Xe (see review by
174 Haner and Schrobilgen (2015) and references therein). Xe-H bond length in Xe-O-H

175 and Xe-C-H compounds is shorter, at 1.7-1.8 Å (Khriachtchev et al., 2008). Moreover,
176 due to the very weak scattering factor of hydrogen, if the additional contribution at

177 2.05 Å was to be attributed to Xe-H, it would imply an extremely high coordination
178 number. Theoretical calculations predict a much more comparable Xe-O bond length

179 of 1.99 Å to 2.29 Å in Xe-doped SiO₂ quartz (Probert, 2010), and of 2.17 Å in Xe-doped
180 fibrous SiO₂ (Kalinowski et al., 2014), two compounds chemically close to the present

181 composition except for their crystalline state. The nature of the Xe-O bond is covalent
182 for these predicted Xe-doped silica crystalline phases, as could also be expected from

183 the sum of the covalent radii of oxygen (0.73 Å) and xenon (1.3 Å). Despite the absence

184 of reported compounds of Xe with Si, Al, Na and K, if Xe was to interact with these
 185 atoms in our experimental samples, one would expect an interatomic distance larger
 186 than 2.4 Å from covalent radii considerations. For these reasons, we attribute the newly
 187 observed peak at 2.05 ± 0.05 Å to the Xe-O interatomic distance. Although no Xe-O
 188 contribution is distinct on ambient T data, whether before or after heating, a shoulder
 189 is still present on $g(r)$ around 2.00 Å unlike for the plain samples (Fig.3B), indicating a
 190 poorer ordering of Xe atoms. The second main difference between plain and Xe-doped
 191 HPG is the stronger intensity of the first sharp diffraction peak on $S(q)$ in the latter,
 192 which indicates an increase of the intermediate range order.

193 3.2. Xenon incorporation

194 In order to estimate the Xe-O coordination number, each particular ion i -ion j
 195 partial distribution function was simulated with the following equations:

$$g_{i,j}(r) = \frac{A_{i,j}}{nS_{\infty}\sigma_i\sqrt{2\pi}} \exp\left(-\frac{(r-d_{i,j})^2}{2\sigma_{i,j}^2}\right) \quad (2)$$

196

$$A_{i,j} = \frac{CN_{i,j}}{\int \frac{4\pi r^2}{\sigma_i\sqrt{2\pi}} \exp\left(-\frac{(r-d_{i,j})^2}{2\sigma_i^2}\right) dr} \quad (3)$$

197 where CN_i is the coordination number of the ion i -ion j contribution, $d_{i,j}$ the corre-
 198 sponding inter-atomic distance, and $\sigma_{i,j} = k\sqrt{d_{i,j}}$ a parameter depending on structural
 199 disorder (Hosemann and Bagchi, 1962) where k is an adjustable parameter (typically
 200 0.08-0.15).

$$S(q) = n \sum_{i,j} c_i c_j f_{i,j}(q) \int_0^{\infty} r(g_{i,j}(r) - 1) \frac{\sin(qr)}{k} dr \quad (4)$$

Figure 3: Structure factors, $S(q)$, of molten haplogranite at high pressures (top panel: runP6, see Supplementary Materials for runs P5, P7 and P11), and corresponding radial distribution functions, $g(r)$ (bottom panel). The dotted lines correspond to the plain sample and the full lines to the Xe-doped sample. The asterisk denotes the additional contribution observed for Xe-doped samples, and attributed to the Xe-O bond.

201 with

$$f_{i,j}(q) = \frac{f_i(q)f_j(q)}{\left[\sum_i c_i f_i(q)\right]^2} \quad (5)$$

202 where c_i is the mole fraction of species i , and f_i is the atomic scattering factor tabulated
203 from Hajdu (1972). Following the approximation adopted by Eggert et al. (2002) for
204 polyatomic liquids, the dependency of $f_{i,j}(q)$ on q can be removed in equation 4 and
205 the experimental $g(r)$ simulated directly against the weighted sum of all individual $g_{i,j}$.

206 Ion-ion contributions at distances larger than 2.5 Å such as K-O and Si-Si are
207 considered negligible below the Xe-O contribution (less than 5% of the peak height), and
208 therefore only Si-O, Al-O, and Xe-O contributions were modelled as separate gaussians,
209 along with a single common contribution for Na-O and O-O both circa 2.5 Å, and with
210 signal at larger distances fitted as a single large contribution (Fig.4). Both Si-O and
211 Al-O contribute to the first peak in $g(r)$, while the Al content is much smaller than
212 the Si content. Consequently, it is not possible to refine independently both Si-O and
213 Al-O contributions. Instead, we fixed the Al-O bond length to 1.77 Å (Drewitt et al.,
214 2015), and its coordination number to either 4.0 up to 1 GPa or 4.3 above 1 GPa. Al-O
215 CN is indeed expected to vary between 4.0 and 4.3 in our experimental 0 GPa-3.8 GPa
216 P -range (Drewitt et al., 2015), and using either of these values provides a conservative
217 estimate of the consequent error on the fitted Si-O coordination number of 0.05, with
218 no significant effect on the fitted Xe-O coordination number. Fitted parameters CN_i ,
219 $d_{i,j}$, and k for Si-O, Al-O and Xe-O contributions at each P - T condition are given in
220 Table 3. For the plain sample (run P3), the fitted CN and bond length (respectively

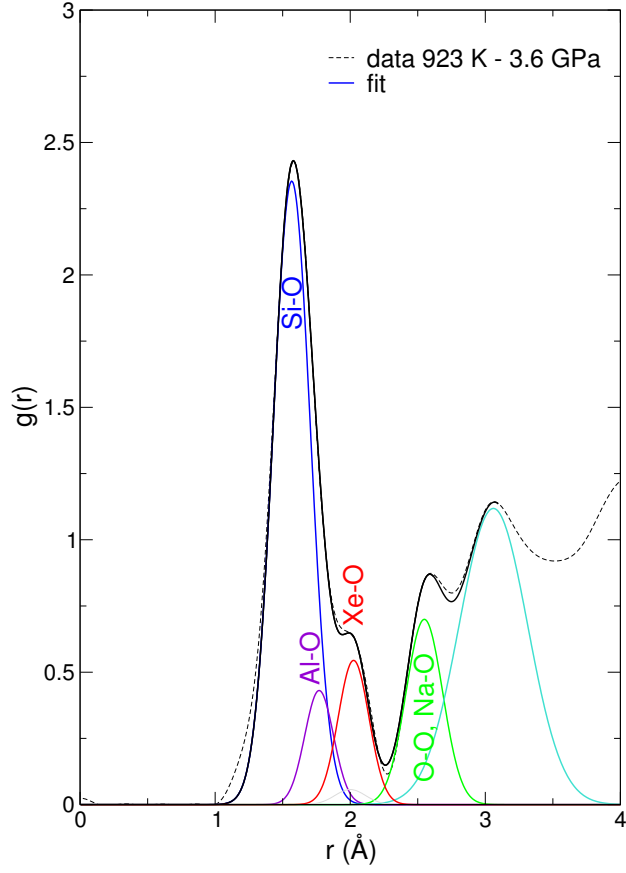

Figure 4: Fit to the experimental radial distribution function, $g(r)$. The black line is the sum of the underlying gaussians; only Si-O, Al-O, and Xe-O contributions were modeled as separate gaussians, along with a common contribution for Na-O and O-O both circa 2.5 \AA , and with signal at larger distances fitted as a single large contribution including K-O and Si-Si at 3.1 \AA ; the grey gaussian is the Mg-O contribution due to slight contamination (1.5 wt%, see section 2.1).

221 4.1 and 1.57 Å±0.02Å) for Si-O are consistent with values reported for SiO₂ glass at
222 similar P , i.e. respectively 4.0 and 1.58 Å (Benmore et al., 2010). Except for the room
223 T data, the fitted Xe-O coordination number is 12 ± 2 , with no dependence on either
224 T or P in the investigated P - T range. Noteworthy is the systematic shift of the fit Si-O
225 bond length upon heating to lower distances compared to the plain sample patterns
226 (cf Table 3). This reduction of the Si-O bond length is accompanied, although less
227 systematically, by a decrease of the Si-O coordination number. This changes in the
228 Si-O contribution might compensate the charge transfer between Xe and O atoms.

229 The high coordination number found here is not consistent with Xe substitution
230 to Si as proposed for quartz in the deep crust (Sanloup et al., 2005; Probert, 2010).
231 Instead, it is consistent with the insertion of Xe in melt rings structure. Amorphous
232 silica is characterized by a broad distribution spread between four and eight-membered
233 rings (Huang et al., 2012), with a characteristic ring size close to 6 in compressed SiO₂
234 melts (Guerette et al., 2015). The center of these 6-membered rings is surrounded by 6
235 oxygens in the ring plane at circa 2.2 Å (Guerette et al., 2015), with a second nearest
236 shell of another 6 oxygens off plane. The presence of Xe could therefore stabilize the
237 6-membered rings of the melt network, hence explaining the observed increase in in-
238 termediate range order in the presence of Xe. The stronger intensity of the first sharp
239 diffraction peak can indeed be interpreted as a narrowed distribution of ring sizes, with
240 6-membered rings being more prominent compared to the broader distribution present
241 in the plain HPG melt. Noble gases enter the melt ring structure, and as a consequence
242 are more soluble in highly polymerized siliceous melts (Carroll and Stolper, 1993). In

Table 3: Fitting parameters derived for Si-O and Xe-O ion-ion contributions for all runs; CN_i : coordination number, d_i : bond length, k_i : width parameter of Gaussian. Error bars for Si-O and Al-O variable parameters do not vary and are given in the top row, they do vary for Xe-O as this contribution varies between ambient T and high T .

243 the case of Kr dissolved in vitreous silica (Wulf et al., 1999), the oxygen atoms lie at
244 a significantly greater distance of 3.45 Å compared to the Xe-O distance of 2.05 ± 0.05
245 Å found in the compressed silicate melts, consistent with Kr being a neutral species in
246 vitreous silica. There are no experimental indications on the valence of Xe in silica-rich
247 melts. Xe has a +5.08 valence in Xe-doped fibrous silica (Kalinowski et al., 2014), the
248 closest crystalline analogue to our silica-rich melts in terms of chemical composition,
249 with a coordination number of 4 and mean bond length of 2.17 Å. Amongst all reported
250 Xe oxides, Xe valence varies from +2.89 in Xe-doped olivine for a coordination number
251 of 3 and bond length circa 2.0 Å (Crépisson et al., 2018), to +8 for Xe in XeO₄ (co-
252 ordination number of 4, bond length of 1.74 Å (Gundersen and Hedberg, 1970)) and
253 K₄Xe₃O₁₂ perovskite (coordination number of 6, bond length of 1.77 Å (Britvin et al.,
254 2016)). From this review, no systematic trend appears between Xe-O coordination
255 number, valence and/or bond length; however the Xe-O bond always has a covalent
256 character, and a minimum valence of +4 for Xe in compressed silicate melts seems a
257 conservative assumption.

258 *3.3. Xe solubility*

259 Our measured solubility values of Xe at 3.5 GPa in molten hydrous HPG, i.e.
260 3.1(0.4) wt% for 7.2 wt% H₂O and 4.0(0.8) wt% for 5.1 wt% H₂O, are respectively
261 5 and 7 times higher than Xe solubility in tholeitic melt (Schmidt and Keppler, 2002).
262 The lower solubility of Xe in the most hydrated HPG glass is consistent with noble
263 gas solubility being highest in the most polymerized melts (Carroll and Stolper, 1993),

264 water being an effective depolymerizing agent in silicate melts. Similarly, Schmidt
265 and Keppler (2002) reported Ar solubility values about 5 times higher in molten HPG
266 than in molten tholeite. The experimental solubility values are however at odds with
267 molecular dynamic calculations (Guillot and Sator, 2012), being a factor of 8 higher
268 for Xe in tholeitic melt, and 10 higher for Xe in HPG melt (Fig.5). We propose that
269 such a strong discrepancy is related to the chemical interaction between Xe and neigh-
270 bouring O atoms that is not considered in theoretical calculations but likely enhances
271 Xe solubility in silicate melts. Indeed, considering a neutral Xe atom implies a larger
272 atomic radius than an oxidized Xe atom, hence the much lower abundance of sites large
273 enough to accommodate neutral Xe atoms that does not match experimentally mea-
274 sured solubilities. Simulations allowing Xe to ionize would be expected to reproduce
275 the solubility data. A structural investigation of Xe environment in basaltic melts using
276 X-ray diffraction as done here for HPG melts is not possible, due to the low Xe solubility
277 for this composition. The very weak Xe contribution to the pair distribution functions
278 would indeed be below noise level. The similar mismatch between experimental and
279 theoretical Xe solubility values in molten HPG and basalt nonetheless indicates that
280 Xe oxidation may as well occur in basalts at depth.

281 **4. Discussion**

282 Xe oxidation in deep magmas and consequent isotopic fractionation may be expected
283 in the following geodynamical settings. Xe oxidation can occur in major crystalline
284 phases of the deep continental crust (Sanloup et al., 2005; Probert, 2010; Kalinowski

Figure 5: Experimental solubility data for Xe; black circles: in tholeiitic melt (Schmidt and Keppler, 2002), red circles: in hydrous haplogranitic melts (this work). Are shown for comparison theoretical calculations by Guillot and Sator (2012) (black diamonds: tholeiitic melt, red diamonds: haplogranitic melt).

285 et al., 2014) and upper mantle (Sanloup et al., 2011; Crépisson et al., 2018). The present
286 experimental results show that Xe oxidation could also occur in magmas generated
287 at subduction zones, following fluid and/or melt release from the subducted plate.
288 Hydrous silicic slab-derived melts which composition is similar to ours occur either by
289 melting of the basaltic crust (Prouteau et al., 2001) or by melting of siliceous sediments
290 (Turner et al., 2012), the latter interestingly having a strong Xe retention (Matsuda and
291 Matsubara, 1989). These melts and their metasomatic products are subsequently found
292 in the continental lithosphere. Xe terrestrial deep cycle is therefore likely controlled by
293 the behaviour of silica-rich materials (i.e. siliceous sediments, polymerized crustal melts
294 and their crystallization products), providing a storage mechanism in these materials
295 at depth. Geochemical tracing of Xe also suggests that Xe is stored in the continental
296 lithosphere (Broadley et al., 2016), including in the deep crust where elemental and
297 isotopic excesses have been reported (Pujol et al., 2011; Holland et al., 2013). Besides
298 deep crustal melts, other obvious Xe reservoirs at depth would be melts trapped at depth
299 as probed by seismological data atop the 410 km (Tauzin et al., 2010), below the 670
300 km (Schmandt et al., 2014) and at the core-mantle boundary (Garnero and McNamara,
301 2008). The latter might be a remnant of the magma ocean, in which noble gases were
302 dissolved (Harper, 1996), explaining the deep mantle signature of heavy noble gases.
303 Subsequent atmosphere ejection (T-Tauri blow-off and impact erosion) resulted in the
304 Xe present-day atmospheric signature being derived from the Xe fraction retained at
305 depth.

306 Xe isotopes are highly fractionated in both terrestrial and martian atmospheres, by

307 30 ‰/amu. Isotopic fractionation in experimental samples remains to be measured in
308 order to quantitatively assess how Xe oxydation at depth may solve the Xe isotopic
309 paradox. However, experiments involving noble gas ionization resulted in mass depen-
310 dent isotope fractionation of Xe of the order of 5-15 ‰/amu favouring heavy isotopes
311 at 1000 K (Kuga et al., 2015). This contradicts the intuition that elements are not
312 isotopically fractionated at high T, as also shown by nitrogen isotopes in metal/melt
313 partitioning experiments with $\delta^{15}N = -3.5 \pm 1.7\text{‰}$ even in the 1900-2100 K range (Li
314 et al., 2016). From bond stiffness considerations, the effect of Xe-O bond formation in
315 silicates is expected to be stronger than simple ionization as it involves more charge
316 transfer ($0 \rightarrow 4$, cf section 3.2) than simple ionization while occurring at similar T
317 (circa 1000 K). Xe oxydation in crystalline silica occurs in a different environment,
318 with Xe being bonded to four oxygen atoms in a planar geometry (Probert, 2010; Kali-
319 nowski et al., 2014). Different bonding environment in crystals and melts may also
320 induce isotopic fractionation, that unlike elemental fractionation, should be preserved
321 in experimental high P - T samples quenched back to ambient conditions.

322 5. Conclusions

323 From *in situ* high energy X-ray diffraction measurements on compressed silicate
324 melts, it is shown that Xe bonds to oxygen in hydrous haplogranitic magmas at depth.
325 The Xe-O bond length is $2.05 \pm 0.05 \text{ \AA}$ and its coordination number of 12 ± 2 , consistent
326 with Xe insertion in 6-membered rings, with 6 oxygen in the ring plane and 6 oxygen
327 off plane. The Xe-O bond is evidenced on pair distribution functions that describe

328 the melt structure, while it is absent for Xe undoped melt. This result provides an
329 explanation for the order of magnitude difference between experimentally measured
330 and theoretically calculated Xe solubility in melts, while the results are in much better
331 agreement for Ar.

332 This result adds to previous studies on Xe retention in minerals at depth, comfort-
333 ing the hypothesis of Xe storage at depth to explain the ‘missing Xe’ paradox. To what
334 extent Xe retention in silicate minerals and melts affects its partitioning in magmatic
335 processes depends on crystal/melt partition coefficients. Measuring Xe crystal/melt
336 partitioning on samples quenched to ambient conditions has proved challenging, as
337 demonstrated by the results spanning 7 orders of magnitude (Heber et al., 2007). In-
338 stead, a comprehensive understanding of Xe environment in melts and major silicate
339 minerals would help to provide a theoretical framework to model Xe partitioning. This
340 method was initially proposed by Brooker et al. (2003), although the authors then
341 assumed zero charge neutrality for Xe, and would need to be revised to consider Xe
342 oxidation and the consequent smaller radius of Xe.

343 This study therefore paves the way for a more systematic study of Xe chemical
344 environment in planetary materials, extended to crystalline phases. Understanding the
345 chemical environment of noble gases in planetary materials seems the most efficient
346 path to solve the fundamental geochemistry of xenon.

347 **6. Acknowledgements**

348 We acknowledge M. Fialin for assistance with the electron microprobe analyses, and
349 H. Khodja and S. Surblé for assistance with the nuclear microprobe analyses. Portions
350 of this research were carried out at the light source PETRA III at DESY, a member of
351 the Helmholtz Association (HGF). This work was supported by the European Commu-
352 nity's Seventh Framework Programme (FP7/2007-2013) under grant agreements no.
353 312284 and 259649 (European Research Council starting grant to C.S.), and from
354 French state funds managed by the ANR within the Investissements d'Avenir pro-
355 gramme under reference ANR-11-IDEX-0004-02 (cluster of Excellence MATISSE led
356 by Sorbonne Universités).
