Abstract—This work presents the performance and transport characteristics of vertically stacked p-MOSFET SOI nanowires (NWs) with inner spacers and epitaxial growth of SiGe raised source/drain. Electrical characterization is performed for NWs with [110] and [100] channel orientations, as a function of both fin width (W_{fin}) and channel length (L). Results show a good electrostatic control and reduced short channel effects (SCE) down to 15nm gate length. Improved effective mobility is obtained for [110]-oriented NWs due to higher sidewall mobility contribution.

Keywords—performance; transport; electrical characterization; vertically stacked nanowire; SOI MOSFET; channel orientation.

I. INTRODUCTION

Multiple gate transistors have been designed to improve the electrostatic control of the gate over the charges in the channel, allowing stronger immunity against short channel effects [1]. Since higher electrostatic coupling is obtained increasing the number of gates and reducing the distance among them, triple gate (3G) and Gate-All-Around (GAA) MOSFETs have demonstrated to outperform short channel FinFETs, attracting interest of both scientific community and semiconductor industry [2].

Nanoscale multiple gate MOSFETs called nanowires, characterized by thin silicon thickness and narrow fin width, have shown to be a good alternative to FinFET technology for the continuity of the CMOS roadmap due to their great performance and scalability [3], [4].

To fulfill higher drive current requests imposed by the International Technology Roadmap for Semiconductors (ITRS), the performance of multiple gate structures have been improved through the development of new technologies and implementation of different materials and process techniques, such as mechanical stress and rotated substrates. While the use of compressive and tensile stress can enhance holes and electrons mobility, respectively [5], [100]-orientated channel can boost n-type NWs current due to higher electrons mobility along (100) sidewalls [6].

Recently, vertically stacked NWs have been successfully fabricated due to advanced process developments. These devices combine reduced SCE and improved on-state current (I_{ON}) due to higher device aspect ratio, as the overall channel width (W_{eff}) is increased and proportional to the number of beams [7]–[9].

In this work, we present the performance and transport of vertically stacked p-FET SOI NWs fabricated with inner spacers and SiGe raised source/drain [9]. The analysis is performed as a function of both W_{FIN} and L, for NWs oriented along [110] and [100] directions. Electrical characterization is performed from I-V and C-V curves to evaluate I_{ON}/I_{OFF} behavior, gate-to-channel capacitance (C_{gc}), effective oxide thickness (EOT), threshold voltage (V_{TH}) roll-off, subthreshold slope (S), DIBL, series resistance (R_S) and effective mobility (μ_{eff}).

II. DEVICES CHARACTERISTICS

Vertically stacked NWs with two levels have been fabricated at CEA-LETI, starting from SOI wafers with 145nm buried oxide thickness and using a replacement metal gate (RMG) process. TEM images of the cross section (a) and the longitudinal section (b) of the studied stacked-NWs MOSFETs are presented in Fig. 1. It is observed that the wire at the bottom presents a Ω-shaped gate while the wire at the top is GAA. Both levels have a 10nm thick Si channel and Si_{0.3}Ge_{0.7}B raised source/drain have been used in order to induce a compressive strain of up to 1% in both top and bottom channels [9]. The transistors have been fabricated along two different crystallographic orientations, [110] and [100], and present a gate stack composed by HfO_2/TiN/W. Further fabrication details of the stacked-NWs studied in this work can

Fig.1. Vertically stacked SOI NW cross section (a) and longitudinal section (b) TEM images.
be found in [9].

In order to extract the EOT resulted from the gate stack deposition after RMG process, capacitance measurements were performed and compared to results obtained from a Poisson-Schrödinger solver considering quantum confinement effects for FDSOI MOSFETs. Fig. 2.a presents $C_{GC}$ as a function of $V_{GS}$ for [110]- and [100]-NWs, $W_{FIN} = 45$nm and $L = 100$nm. The solid line indicates the modelled result considering EOT of 1.2nm. After fitting the experimental C-V curves, 1.2nm of EOT has been extracted for both transport orientations. Fig. 2.b presents $C_{GC}$ as a function of $W_{FIN}$ for NWs biased at the same gate voltage overdrive ($V_{GT} = V_{GS} - V_{TH} = -1$V). The linear behavior, highlighted by the dashed lines, allows to conclude that EOT is sustained with $W_{FIN}$ scaling and channel orientation, indicating uniform and well-controlled gate stack deposition process.

III. RESULTS AND DISCUSSION

Fig. 3 presents the normalized drain current ($I_{DS}/L$) as a function of the gate voltage ($V_{GS}$) for [110] (0°) and [100] (45°) NWs in multiple finger structures (50 fins), with $L = 30$nm and 100nm, at small (a) and strong (b) horizontal electric field, $V_{DS}$ of $-40$mV and $-0.9$V, respectively. Higher drain current is observed in [110]-NWs, as expected for p-FETs. Indeed, holes mobility is enhanced in the (110)-oriented sidewalls in comparison to (100) plan [10]. Additionally, the SiGe source and drain induce a uniaxial compressive stress, which may become detrimental in narrow p-NWs with [100]-oriented channel. As reported in [11], the longitudinal piezoresistive coefficient of [100]-oriented NWs are lower than zero (see Fig. 5 in [11], where $\pi_{LW}[100]<0$), which degrades even more the holes mobility in such narrow devices. From the logarithmic scaled curves in Fig. 3, it is possible to state that neither by reducing $L$ from 100nm to 30nm nor by decreasing $V_{DS}$ down to $-0.9$V significant degradations of the subthreshold characteristics are observed.

Fig. 4 presents $I_{OFF}/W_{eff}$ as a function of $I_{ON}/W_{eff}$ (a) and $I_{OFF}/W_{FIN}$ as a function of $W_{FIN}$ (b) for $L = 30$nm, at $V_{DS} = -0.9$V. $I_{OFF}$ and $I_{ON}$ have been extracted at $V_{GS} = 0$ and $-0.9$V, respectively. For $W_{FIN}$ ranging between 15 and 30nm, $I_{ON}/W_{OFF}$ of [110]-NWs reaches up to 450$\mu$A/µm, while $I_{OFF}/W_{FIN}$ can reach up to 2500$\mu$A/µm for $W_{FIN} = 15$nm. The normalization of $I_{ON}$ by the effective channel width (calculated by $4.1\delta_{G} + 3.6W_{FIN}$) has an important physical meaning, once it aims to calculate the amount of current per unit of length that flows considering all the seven conduction channels formed in both bottom and top wires. On the other hand, the normalization of $I_{OFF}$ by $W_{FIN}$ allows a comparison from the point of view of the top area, highlighting the benefit of increasing $W_{FIN}$ by stacking.
2 levels of NWs. Moreover, one can observe similar $I_{OFF}$ for both channel directions and $I_{OFF}/I_{ON}$ ratio in the order of $10^4$, higher for 0° NWs and increasing with $W_{FIN}$ reduction.

Fig. 5.a shows the $V_{TH}$ behavior with $W_{FIN}$ and $L$, extracted by the second derivative method, at $V_{DS} = -40$ mV. Improvements for narrower NWs and very small $V_{TH}$ roll-off (lower than 60mV) is observed while reducing $L$ down to 15nm. Figs. 5.b and 5.c show, respectively, $S$ and $|DIBL|$ results as a function of $W_{FIN}$ and $L$. A small subthreshold slope degradation is obtained with channel shortening. For [110]-NWs with $W_{FIN}$ of 25nm, $S$ is lower than 88mV/dec down to $L = 15$nm. Through both $S$ and $|DIBL|$, it is observed approximately constant dependence with $W_{FIN}$ for $L = 100$nm and 60nm, reduced SCE for narrower NWs for $L = 30$nm and that both [110]- and [100]-NWs exhibit similar results, as predicted by the logarithmic scaled curves in Fig. 3. Besides, $|DIBL|$ is lower than 100mV/V for [110]-oriented NWs with $W_{FIN} = 25$nm and $L$ down to 15nm.

Fig. 6 shows the results for the total resistance ($R_T = V_{DS}/I_{DS}$) as a function of the inverse of the NW gain ($1/V_{TH}$), for [110] and [100]-NWs. $W_{FIN}$ of 15, 30 and 65nm, $V_{DS} = -40$mV and $V_{GT} = -1$V. From these curves, $R_S$ is extracted following the $Y$-function method [12]. Good linearity of the data points is demonstrated by the solid lines, which lead to series resistance values around 140 and 360$\Omega$.µm, for [110] and [100]-NWs, respectively. The linear curves observed in Fig. 6 cross the y-axis at the same $R_T$, $W_{OFF}$ value for all $W_{FIN}$ studied, indicating that $R_S$ scales with $W_{FIN}$ for the entire range of $L$, from 100nm down to 15nm.

The hole mobility as a function of the inversion carrier density ($N_{inv}$) extracted by split-CV technique [13] for $L = 100$nm and $W_{FIN} = 15$nm is shown in Fig. 7. The maximum mobility is found equal to 63 and 32cm²/V⋅s for standard and rotated NWs, respectively. Moreover, the inner figure shows that the $\mu_{eff}$ ratio between both [110] and [100]-NWs is close to 2, which agrees with the $I_{ON}/W_{OFF}$ results obtained in Fig. 4.

Fig. 8 presents $\mu_{eff}$ as a function of $L$ (a), extracted by $Y$-function method, and as a function of $W_{FIN}$ (b), extracted by split-CV technique, for several NWs, at $N_{inv} = 0.8 \times 10^{13}$cm⁻². Standard NWs show strong $\mu_{eff}$ degradation for $L < 60$nm while rotated NWs present a constant, but lower, mobility down to $L = 30$nm. Besides, $\mu_{eff}$ shows improvements of up to 17% with $W_{FIN}$ reduction for [110]-NWs, while [100]-NWs

![Fig. 5](attachment://fig5.png)

![Fig. 6](attachment://fig6.png)
Excellent SCE control (small $V_{TH}$, $S$ and DIBL degradations down to 15nm gate length) have been obtained for both [110] and [100]-oriented NWs due to good electrostatic coupling and channel control provided by the sum of Ω-Gate and GAA wires.

On the same way as for 3G NWs, [110] orientation is better for p-type stacked NWs due to hole mobility improvements in (110)-oriented sidewalls.
