13 Abstract: In this work, a pH-responsive polyelectrolyte 2-(N, N-dimethylamino) 14 ethyl methacrylate (PDMAEMA) was grafted onto the cotton fabric by surface-initiated atom transfer radical polymerization by activator regenerated electron 15 16 transfer (SI-ARGET ATRP). Then, the grafted cotton fabric was dyed by reactive dyes. 17 SEM, XRD, FT-IR, TGA and whiteness test were investigated to characterize the PDMAEMA grafted cotton fabric. Meanwhile, the dyeing temperature, fixed 18 19 temperature and pH value in the dye bath were carried out to explore the optimum 20 dveing process. Finally, the mechanism of salt-free dveing of PDMAEMA grafted 21 cotton fabric is proposed. The results showed that the cotton fabric was successfully 22 grafted by PDMAEMA, which presents excellent dye up-take, fixation yield, K/S value 23 and dyeing uniformity and color fastness under the dyeing temperature of 30 °C, the 24 fixed temperature of 60 °C, and the pH value of 6. Moreover, the pH-responsive process 25 not only realizes salt-free dyeing, but also increases the dye up-take, fixation yield and the dye levelness due to the migration dyeing process. This work provides a promising 26 27 route to realize the salt-free dyeing of reactive dye on cotton fabric, which is beneficial 28 to environment protection for the significant reduced content of dye and salt in waste 29 water.

32

33 **1. Introduction**

34 As the improvement of people's awareness for environment protection and 35 increasingly stringent government regulations, the textile industry is seeking more 36 environmentally friendly processes to meet the needs of cleaner production.[1, 2] 37 Cellulose fiber can meet the requirements of the use of cellulosic fibers as a renewable 38 material possessing satisfying properties. For dyeing cellulose fiber, the reactive dyes are widely used due to the high wet rubbing fastness and bright colors.[3-5] During the 39 dveing process, Cellulose fiber surface was negatively charged in water bath. Then the 40 41 electrostatic repulsion between the fibers with anionic reactive dyes makes the 42 absorption of dye molecules on the fibers difficult.[6] Therefore, the traditional reactive 43 dyeing needs to add a large amount of inorganic salts (such as NaCl, Na₂SO₄) to shield the negative surface of the fiber for dyeing easily.[7-11] However, the inorganic salts 44 45 are almost all retained in the waste liquid after dyeing contains, which causes serious water pollution issue; moreover, the salt in the sewage penetrates into the soil, leading 46 47 to the salinization problem of the land.[10, 12, 13] Therefore, the salt-free or low-salt dyeing technology of anionic dyes has attracted much attention, to replace traditional 48 49 dyeing process with salt as dyeing accelerant.[14, 15]

50 Considering the shielding mechanism of the inorganic salt in the dyeing bath, the 51 affinity between dyes and fibers is the key to realize the salt-free dyeing. At present, four main methods are studied: the development of substitute salt and salt-free dyeing 52 auxiliaries;[16] the modification of molecular structure of the reactive dye;[17] using 53 54 new machinery to improve the dyeing process to reduce the use of salt;[18] and the 55 cationization of the fiber to achieve the purpose of salt-free dyeing.[19-21] One type of non-reactive cationic modification is the physical adsorption of the fiber to endow the 56 fiber positively charged. However, due to the uncontrollable molecular weight, the 57 58 dyeing fabric has low leveling property, poor color fastness and darkening of the color. 59 Therefore, among these methods, the formation of cationic groups on the surface of 60 cellulose fibers by chemical modification is the most promising for salt-free or low-salt dyeing.[22, 23] The cation modification is mainly through attaching a cationic 61 62 chemical (mainly a nitrogen-containing compound) onto the surface of the cellulose 63 fiber, which makes negative charges of the fiber hidden and limited by the addition/substitution of cations. [24-26] The modified cotton can be dyed with an 64 65 anionic dye under neutral or weakly acidic electrolyte-free conditions.[27, 28]

66 Up to now, there are many types of modifiers reported for the cationization 67 modification of cotton fabrics. Abkenar et al. [29, 30] grafted a large amount of primary and tertiary amino-modified PPI dendrimers by using a crosslinking agent. The 68 69 modified cotton fabric obtained high dye utilization and color strength without salt. 70 Wang et al. [31] synthesized a new amino-terminated hyperbranched polymer (at-HBP). 71 The results showed that the K/S value of the modified ramie fabric was comparable to 72 traditional salt dyeing without the electrolyte. The friction fastness of the modified 73 ramie fabric was excellent. Tuba Toprak et al. [22] treated 4-vinylpyridine onto cotton fabric. The effects of the amount of polymer and the different treatment methods on the 74 75 dyeing performance of the fabric were systematically investigated. Their method was 76 confirmed can be used as an alternative to traditional dyeing. However, there are still 77 some problems for with the reactive cationic modifier. Besides their low utilization rate, 78 their relatively harsh reaction conditions (strong alkali, strong acid, high temperature, 79 etc.) usually have a great influence on the fabric properties. In addition, due to the

positive electrical properties of the modified fabric, the dyeing rate is easy to causeuneven dyeing in the early stage of dyeing.

In the present work, a pH-responsive polymer PDMAEAM was grafted onto the 82 surface of cotton fabric by SI-ARGET ATRP method. The effects of monomer dosage, 83 synthesis time on fabric graft ratio and fabric whiteness were investigated. This 84 85 responsive polymer mechanism of action was explored. During the dyeing stage, the 86 graft polymer is protonated and positively charged by adjusting the dye bath to weak acidity. The positively charged polymer shields the negative charge on the cellulose 87 88 fiber surface. Negatively charged anionic dyes are adsorbed onto positively charged 89 fibers due to electrostatic attraction. In the following fixation stage, because the H⁺ in 90 the dyeing bath are neutralized and then the dye bath turns to be alkaline, the graft 91 polymer PDMAEMA is deprotonated with the increase of the temperature and the 92 addition of alkaline Na₂CO₃. The negative charge shielding effect on the surface of the 93 cotton fabric disappears and the surface of the fiber exhibits a negative charge. The dye 94 adsorbed by the electrostatic attraction is returned to the dye bath, and secondary 95 dyeing occurs, which increases the transfer dyeing and improves the dyeing levelness. 96 Additionally, the dyeing process conditions were optimized: the effects of pH, dyeing 97 and fixing temperature on fabric dyeing performance were investigated. Finally, the 98 adsorption isotherms of fabric dyeing were explored. After our cationization 99 modification with PDMAEMA on the cotton fabric, the leveling property and the K/S 100 value of the dyed fabric are improved compared with the traditional dyed fabric.

101

102 2. Results and discussion

PDMAEMA is grafted onto the cotton fabric by SI-ARGET-ATRP method as shown in Fig.1, divided into two steps. The first one is the substitution reaction between the hydroxyl group on the cellulose fiber and the bromine group of the initiator. The initiator is grafted on to the cotton fabric firstly. Then, the monomer DMAEMA is polymerized under the participation of the reducing agent and the catalyst, which directly happens on the surface of the cotton fabric. Therefore, the cation-modified cotton fabric with PDMAEMA is obtained.

114

111

115 **2.1 Characterization of modified cotton fabric**

116 2.1.1 FT-IR test

117 Fig.2 shows the FTIR spectras of PDMAEMA and cotton fabrics before and after grafting. The characteristic peaks of PDMAEMA are as follows: the peak at 1724 cm⁻¹ 118 119 is the stretching vibration of γ C=O; the peaks appeared at 2827 cm⁻¹ and 2774 cm⁻¹ are corresponding to the C-NH₃ vibration; the peak at 1265 cm⁻¹ and 1449 cm⁻¹ are the NH₂ 120 vibration and symmetric bending vibration of CH₂, respectively; the stretching 121 vibration peak of γ C-N appears at 1265 cm⁻¹. Compared with the untreated cotton 122 fabric, the additonal characteristic peaks of PDMAEMA appeared on the FTIR spectra 123 of cotton-PDMAEMA fabric. These results certify the PDMAEMA is successfully 124 125 grafted onto the cotton fabric.

127 Fig. 2 FI-TR characterization of PDMAEMA 、 cotton fabric before and after grafting

128 2.1.2 SEM test

SEM images of the raw cotton fabric and the graft-modified cotton fabric are shown in Fig.3a and 3b. It can be seen that the surface of the raw cotton fabric is relatively smooth and the modified fabric has a film covering the surface of the cellulose fiber. No obvious cracks can be observed indicating that PDMAEMA is successfully grafted onto the cotton fabric.

- 134
- Fig. 3 SEM images of the raw cotton fabric (a) (c) and the modified cotton fabric (b) (d)
 under various magnifications,
- 137 2.1.2 XRD and TG test

Fig. 4a shows the XRD spectra of the fabrics before and after the cation modification. The characteristic diffraction peaks of two fabrics have no obvious difference, showing the surface modification does not affect the crystal form of the

cotton fabric. The crystallinity is relative to the molecular arrangement and tightness. In 141 142 detail, loose molecular arrangement of the fiber leads to small crystallinity, then easy 143 swelled in the dyeing bath. Therefore, the effect of the modification on swelling property of the cellulose fiber is negligible. Fig. 4b is thermogravimetric analysis (TGA) 144 curves before and after the modification. The modified cotton fabric shows two thermal 145 146 decomposition peaks at 210°C (sublimation of PDMAEMA polymers) and 290°C 147 (sublimation of cotton), respectively, while the thermal decomposition temperature of 148 the raw cotton fabric is at about 290°C. Therefore, compared to pure cotton, the appearance of additional peak at 210°C in modified cotton fabric proves the 149 150 combination of cotton and PDMAEMA modifier. Fig 4c shows the effect of the yield of 151 the grafting on the water retention value of cotton fabrics, indicating that the yield of 152 the grafting of the fabric has a small effect on the water retention performance of cotton fabrics 153

158 **2.2 Dyeing performance**

Further, the effect of grafting rate, dyeing bath pH, dyeing temperature and fixation temperature on dyeing performance of modified cotton fabrics were investigated. Moreover, the dyeing thermodynamics and kinetics of the modified cotton fabrics were discussed to illustrate the dyeing mechanism.

163

164 2.2.1 Dyeing process

165 The schematic diagram of the dyeing procedure of the modified cotton fabric with 166 reactive dyes is shown in Fig. 5. It can be seen that at the beginning of the dyeing process, the addition of acetic acid at a lower temperature makes the dye bath weakly 167 168 acidic. The polymer PDMAEMA is positively charged and protonated to achieve a shielding function to the negative charge on the surface of the cotton fiber. After the 169 170 anionic reactive dye is added, they are directly attracted to the positively charged cotton fabric. The dye molecules were adsorbed by modified cotton fabric through coulomb 171 172 attraction. Then, they diffuse into internal of the fiber and complete the combination 173 of dye molecules and modified cotton fabric. The entire dyeing process were achieved by Langmuir adsorption. After Na₂CO₃ added to the dye bath at fixation stage, H⁺ is 174 175 neutralized in the alkaline environment, which leads to the deprotonation of the 176 polymer PDMAEMA. Therefore, the shielding effect disappears and the fiber surface

expose the negative charges. Then, the dyes adsorbed on PDMAEMA bonded by 177 electrostatic attraction during the dyeing stage are off from PDMAEMA and into the 178 179 dye bath, which happen to the secondary dyeing(The positive surface of the fiber is higher in higher grafting rate of fiber surfaces, leading to a higher amount of dve 180 molecules absorbed by the fiber and the polyelectrolyte. Therefore, polyelectrolyte is 181 182 deprotonated and more dye molecules removed from the higher grafting rate fiber 183 surfaces. And the dye molecules transfer to lower grafting rate fiber surfaces). This 184 process improves the migration dyeing process and benefits significantly the dyeing 185 levelness.

When dyeing the modified fabric, the dyeing conditions have a great influence on
the dyeing performance of the fabric, so the effect of the dyeing temperature, dyeing
bath pH and polymer graft ratiowas investigated.

189

190

191 Fig. 5 Dyeing procedure of the modified cotton fabric with reactive dyes.

192 2.2.2 Effect of the yield of the grafting of PDMAEMA on dyeing performance

Cotton fabrics with different the yield of the grafting of 4.1%, 5.1%, 6.3%, 7.6%,
8.7%, 9.4%, 10.5% and 11.9% were prepared (the detail is shown in Supporting
Information). The modified cotton fabrics with different grafting rates were dyed under
the same conditions.

As shown in Fig. 6a, when the graft ratio is less than 7.6, the dye up-take, reaction rate and fixation yield increases with the increase of the graft ratio. When the graft ratio is more than 7.6, they are slowly reduced. The change tendency of K/S value is related to the color strength which is consistent with the dye up-take, reaction rate and fixation yield, as the bar chart shown in Fig. 6b. On the other hand, the curve in Fig. 6b is the relative unevenness of the fabric with different graft ratios.

Fig. 6c shows the surface zeta potential of cotton fabrics with different graft ratios under weakly acidic condition at pH = 6. It can be seen that the zeta potential enhances with the increase of graft ratio. For the dyeing process, cotton fabrics with more positive zeta potential can adsorb the dyes more strongly, so the dye up-take is higher and higher with the increase of graft ratio, when it is less than 7.6. The leveling property of the fabric also becomes better. That might be ascribe to the different densities of the graft modifier on the surface. At low grafting rate, the fabric did not reach its optimum

grafting rate, and the molecular distribution of the graft polymer was sparse, so that the 210 211 dye absorption capacity of different parts of the fabric was different, resulting in a 212 decrease in the levelness of the fabric. However, after the graft ratio exceeds 7.6 (dveing rate exceeds 98%), with the grafting rate increasing, the amount of dye 213 molecules absorbed by the grafting polymer increasing, and the amount of dve 214 215 molecules absorbed by the fiber decreasing. At the same time, due to the van der Waals 216 force, the polymer also adsorbs dye molecules, which increases floating color on the fiber surfaces. Therefore, the reaction rate decreases and the evenness becomes worse. 217 In addition, during the fixation stage, the dye molecules off from PDMAEMA are much 218 219 more than ones fixed on the fiber by covalent bond, which further leads to the decrease 220 of the dye up-take, reaction rate and fixation yield.

221

Fig.6 PDMAEMA graft ratio versus (a) reactive dye uptake (E%) and fixation yield
(F%), (b) dyed fabric surface color depth (K/S) and the relative unevenness (Sr) and (c)
effects of Zeta potential.

226 2.2.3 Effect of starting dyeing pH on dyeing performance

The modified cotton fabric with graft ratio of 7.6 typically was dyed by in the dye bath under various starting dyeing pH in the range of 3-7.

229 The molecular structure of PDMAMEA polymer consists of a tertiary amine 230 group which can undergo a "protonation-deprotonation" transition, exhibiting different states as pH of the solution change. This endows them with different 231 232 hydrophilic-hydrophobic balance values, exhibiting pH sensitivity. Fig. 7a shows the 233 surface zeta potential of the raw cotton and the modified cotton fabric under different 234 pH. The zeta potential of the raw cotton fabric is negative under different pH condition, while the PDMAEMA-grafted modified cotton fabric is positively charged under acidic 235 236 conditions. Under strong acidic condition (pH in the range of $3 \sim 5$), the zeta potential of 237 the modified cotton fabric has little change with the increase of pH. After the pH 238 increased to 6, the surface zeta potential of the fabric decreases rapidly with the 239 increase of the dyeing bath pH. When pH reaches to ~9, the zeta potential decreases to the negative value. The zeta potential is closely relative to the degree of protonation of 240 241 the cotton fabric. The degree of protonation of the the modified cotton fabric can be 242 calculated by Henderson-Hasselbalch as shown in Formula (1). Accordingly, the 243 degree of protonation is 99.8% at pH=5, 98.04% at pH=6 and 0.99% at pH=9.

244
$$pH = pK_a - \log\frac{\beta}{1-\beta} \tag{1}$$

where pKa = 7.7, which is the apparent dissociation constant of the polymer in water, and β is the degree of protonation of the polymer at a certain pH. Therefore, if the starting pH of dyeing bath is in the range of 3~7, the zeta potential of the modified
cotton fabric can make sure to keep a relatively highly positive, which is beneficial to
dyes absorption at the beginning of dyeing process.

Fig. 7b reflects the various starting dyeing pH from 3 to 7 effect on the dye 250 up-take and fixation yield. The pH of the dye solution was adjusted by adding glacial 251 252 acetic acid at the beginning of the dyeing. It can be seen that at the starting dyeing pH \leq 253 6, the dye up-take and fixation yield changes unobvious. They decrease with the 254 increase of the starting dyeing pH. Because when the starting dyeing pH is ~7, the zeta 255 potential of the fabric surface is low as shown in Fig. 7a, the degree of protonation of 256 the graft polymer is relatively reduced. So ionic bond between cationic cotton and 257 anionic reaction dyes is weak, resulted in a low dyes absorption at the beginning of 258 dyeing process, then a low dye up-take and fixation yield.

260

Fig. 7 (a) Surface zeta potential of the raw cotton fabric and the modified cotton fabric
at different pH; pH value versus (b) reactive dye uptake (E%), fixation yield (F%)and
dyed fabric surface color depth (K/S).

264 2.2.4 Effect of temperature on dyeing performance

265 The effect of dyeing temperature and fixing temperature are discussed on dyeing performance by the dye up-take, fixation yield, K/S value and relative unevenness of 266 the fabric. As shown in Fig. 8a, the dyeing temperature has an important effect on the 267 dve up-take and fixation yield of the modified cotton fabric. They increase first and 268 269 then decrease with the increase of the dyeing temperature, which is consistent with the 270 K/S value tendency. Fig. 8c reflects the zeta potential of the modified fabric surface 271 under various temperature. On one hand, during the dyeing stage, the polymer is protonated. The macromolecular chain stretches the macromolecular segment due to 272 the repulsive force between the positive charges. On the other hand, at lower 273 274 temperature, the molecules chains also elongate and the protonation sites is increased. 275 And the degree of protonation increases correspondingly during the dyeing process, as 276 shown in Fig. 8c, the zeta potential is relatively high, which causes the higher attraction 277 force to dyes. When the temperature increases, the polymer molecular chain shrinks, the contact area between PDMAEMA and H⁺ decreases, which leads to the decrease 278 279 of the cotton protonation degree and dye up-take, fixation yield and K/S value. It's 280 noteworthy that the K/S value in our work can be up to ~40, while the traditional salt dyeing K/S value is only ~15, which can achieve the requirement of dyeing dark color
at low concentration, significantly saving cost and reducing pollution. Herein, the
optimum dyeing temperature is 30 °C.

Fig. 8b shows the effect of fixing temperature on the dye up-take, fixation yield, 284 K/S value and leveling property of the modified cotton fabric. As the fixation 285 286 temperature increasing, both the internal molecular motion of the fiber and the 287 reactivity of dye molecules increases, which is beneficial to the diffusion of the dye into the fiber. Thus, the dye up-take, fixation yield, K/S value are gradually increased 288 289 when the fixation temperature ≤ 60 °C. However, when the fixation temperature 290 continues to increase, the greater amount of dye hydrolysis leads to the low dye up-take, 291 fixation yield, K/S value. Therefore, the optimum fixing temperature is 60 °C.

Fig. 8 The effect of dyeing temperature (a) and fixing temperature versus (b) on dye
up-take (E%), fixation yield (F%) and dyed fabric surface color depth (K/S), (c)
temperature on zeta potential of modified cotton fabric.

297 2.2.5 Effect of pH-responsiveness on leveling property

As shown in Table 1, the dyeing unevenness of the modified cotton fabric in our work keeps substantially below 0.3 under various conditions, which is superior to conventional salt dyeing.

301

302 Table 1 leveling properties of raw cotton fabric and the modified cotton fabric

Sample	Unmodified	modified		
Reactive blue KN-R	0.369	0.231		
Active golden K-2RA	0.336	0.221		
Reactive brilliant red M-8B	0.318	0.205		

303

The fixation stage is key for the leveling property of the modified cotton fabric. As 304 well known, if cotton was modified by non-responsive cationic, the cationic cotton and 305 306 reactive dye molecules will be combined by ionic bonds after dyeing process. The 307 uneven treatment of the cationic modifier will directly cause the uneven dyeing. In this 308 study, the cotton was treated by responsive cationic, which has a better leveling than traditional non-responsive cationic. As shown in Fig 9, H⁺ will be neutralized after 309 adding Na₂CO₃ (alkaline environment), leading to the deprotonation of the polymer 310 311 PDMAEMA. Therefore, the shielding effect disappears and the fiber surface expose the negative charges. Then, the dyes adsorbed on PDMAEMA bonded by electrostatic 312

attraction during the dyeing stage are off from PDMAEMA and into the dye bath, dyes 313 314 transfer from high concentration to low concentration and happen to the secondary 315 dyeing (The positive surface of the fiber is higher in higher grafting rate of fiber surfaces, leading to a higher amount of dye molecules absorbed by the fiber and the 316 polyelectrolyte. Therefore, polyelectrolyte is deprotonated and more dye molecules 317 318 removed from the higher grafting rate fibrer surfaces. And the dye molecules transfer to 319 lower grafting rate fiber surfaces). This process improves the migration dyeing process 320 and benefits significantly the dyeing levelness.

321

322 323

Fig. 9 Schematic diagram of polymer response process

324 2.2.6 Dyeing rate curve

The traditional salt dyeing and salt-free dyeing in this work were carried out under the same condition. Fig. 10a shows the dyeing rate curves of salt-dyed and modified cotton fabrics with salt-free dyeing. The modified cotton fabrics have a fast dyeing speed in early stage. The dyeing rate reach to maximum after 30 minutes, then gradually decreases with the time extending. With the dye bath heated to fixation stage, dye molecules separate from the fabric for secondary dyeing, and the dye uptake rate decreases slightly before fixing.

332 Fig. 10b and 10c show the dyed fabrics images through traditional reactive dyeing process with salt and the salt-free reactive dyeing of modified cotton fabric with 333 PDMAEMA. It can be seen that the dyeing color of modified fabric is much deeper and 334 335 brighter than traditional dyeing with salt. As for the pictures of the waste liquid after 336 dveing of traditional salt dveing process (Fig. 10d), the dve bath of the salt-free dveing of modified cotton fabric with PDMAEMA (Fig. 10e) becomes clear and transparent, 337 illustrating the higher dye up-take, while the waste liquid of traditional reactive dyeing 338 339 with salt retains a amount of dye and salt. This is a crucial improvement for the reactive 340 dyeing, which produce the dyeing waste liquid with no dyes and salt, avoid environmental pollution and reduce the cost of dyeing waste liquid and sewage 341 342 treatment.

Fig. 10 The dyeing rate curves (a) and the dyed fabrics images through traditional salt
dyeing process (b) and the salt-free dyeing of modified cotton fabric with PDMAEMA
(c), the pictures of the waste liquid after dyeing of traditional salt dyeing process (d)
and the salt-free dyeing of modified cotton fabric with PDMAEMA (e).

349 To better understand the color difference of reactive dyes on modified and 350 unmodified cotton fabrics. We performed some dyeing performance tests shown in Tables 2 (E%, F%, L*, a *, b*, c*, K/S and Sr). It can be seen that 351 352 Cotton-PDMAEMA's dye up-take (E%) and fixation yield (F%) are much higher than 353 those of unmodified cotton fabric, showing a better dyeing effect. Because the K/S 354 value of dyed fabric is higher than that of conventional salt dyeing, therefor, the 355 brightness is slightly lower than that of salt dyeing (the dyeing depth is inversely proportional to the brightness). In addition, Cotton-PDMAEMA has a higher a * value. 356 357 This is because the dyeing K / S value of the modified cotton fabric is higher than the 358 conventional salt dyeing, so the chroma is higher.

Table 2 Comparison of dyeing performance of reactive dyes on untreated and treated
 360 cotton

361

362

363 2.2.7 Dye sorption isotherms

364 Fig. 11 shows the relationship between the equilibrium dye concentration (C_s) of the three reactive dyes and the equilibrium adsorbed dye amount (C_f). By comparing 365 the correlation coefficient values (R₂) obtained from the Langmuir and Freundlich 366 367 isotherm models (in Table 3) and fitting the model to the experimental data, it can be 368 concluded that a good agreement with Langmuir equation. $R_L > R_F (> 0.99)$ reflects the 369 adsorption process between three reactive dyes and the modified cotton fabrics. This 370 suggests that Langmuir model can be used to fit experimental data better than the 371 Freundlich model. According to the Langmuir adsorption model, the adsorption of 372 anionic dyes could be related to Coulomb attraction until the surface functional site (-NH₃⁺) is completely occupied, and then the dye diffuses into the fiber cavity. 373
