Abstract

Gas entrainment from surface swirls is characterized using water experiments. A free surface shear flow is generated in an open channel flow. A suction nozzle is set at the bottom of the test section to induce a downward flow and provoke gas entrainment. An important originality of these experiments is the possibility to change the inlet condition so as to generate different turbulent shear flows. This is done by adding obstacles of different sizes and shapes at the end of a flat plate separating the inlet flow from a “stagnant” water area. Velocity fields and profiles, measured with the PIV technique, are provided to describe the inlet conditions corresponding to various geometries and flow rates. Gas entrainment mapping are established from direct observations of the different flow configurations. These new results show that the threshold for the suction velocities required to entrain gas are similar for the configurations with small obstacles and the flat plate configuration triggering a standard shear flow. Increasing the size of the obstacles promotes gas entrainment and reduces the threshold values of the suction velocity to trigger gas entrainment. Shadowgraphy with image processing is used to present new results characterizing the geometrical properties of surface swirls and the quantity of gas entrained. Inlet configurations with obstacles generate larger surface swirls which move upstream from the suction nozzle centre whereas they are situated downstream with the flat plate configuration. Moreover, dimensionless power laws are found to be good approximations for the surface swirl width and the quantity of gas entrained. In addition to provide new insights about gas entrainment in analytical configurations relevant to Sodium cooled fast nuclear reactor, these results should provide different test cases for the validation of MCFD codes, e.g. TRIO-U, NEPTUNE-CFD.

1. Introduction

Gas entrainment has been identified as a possible safety issue in Sodium cooled fast reactors (NaSFR). It can capture gas from the free surface to the bottom of the vessel. This may lead to the accumulation of gas pockets under the core of the reactor (Takahashi *et al.*, 1988; Tenchine, 2010; Tenchine *et al.*, 2014). When these gas pockets get through the core, it can disturb the nuclear reaction and damage the combustible rods. This gas entrainment phenomenon is produced by the combination of existing turbulent structures close to the free surface, such as eddies, and the downward flows created by the suction of hot liquid sodium by the intermediate heat exchangers.

Many experimental facilities have been designed to investigate this phenomenon in relation to the nuclear application. Most of them are water experiments and a brief history can be given.

Baum and Cook, 1975 begins to study the problem through a cylindrical glass apparatus. Here the eddy structure is generated by introducing the flow with a tangential inlet pipe. The liquid exits through an outlet pipe at the centre of the bottom of the cavity. Four liquids were investigated: water, white spirit, Freon 113 and sodium. They

determinate the onset of gas entrainment for the four liquids.

Flow mechanisms of air entrainment was also studied by Takahashi *et al.*, 1988 through an experimental set up close to that used by Baum and Cook, 1975 The novelty of their rig and experiments is the possibility to add a forced circulation by turning the cylindrical cavity. In particular, they showed that an air core with break up bubbles changes to a continuous air core with an additional forced circulation.

In these experimental investigations, the gas entrainment is maintained continuously whereas it appears intermittently in NaSFR. Moreover, Kimura *et al.*, 2008 have performed experiments in a partial model of the Japan Sodium cooled Fast Reactor¹ to show that gas entrainment results from the combination of the wake of obstacles, the presence of shear flows and the suction flow.

Then, to study intermittent gas entrainment, new analytical experimental facilities have been designed so as to isolate the key mechanism of turbulent shear flows combined with flow suction, e.g. Ezure *et al.*, 2011, 2008, Kimura *et al.*, 2009 and Cristofano *et al.*, 2014. These new design

¹ Their choice of the 1/1.8 scale was based on the works of Eguchi *et al.*, 1994 and Eguchi and Tanaka, 1994.

experiments are based on open channel flows. To produce turbulent structures, a shear flow is generated in the middle of the channel. This is realized by separating the main flow from a water dead zone using vertical plates at the inlet and outlet of the channel. The downward flow is generated by flow suction through a nozzle placed at the bottom in the centre of the channel. This combination can produce (or not) gas entrainment through the suction nozzle according to the chosen flow parameters. Such experiments provide the occurrence map of gas entrainment according to flow parameters, *i.e.* inlet velocity, outlet velocity and suction velocity. Moreover, Kimura *et al.*, 2009 have investigated both sodium and water fluids using the same test section to demonstrate that water experiments simulated well the onset conditions of gas entrainment in sodium.

Gas entrainment experiments have also been performed in liquid metal, *e.g.* Vogt *et al.*, 2015 to support the validation of numerical codes.

It is worth mentioning that gas entrainment is also a topic relevant to the automobile industry in the context of the water box (Recoquillon, 2013; Recoquillon *et al.*, 2011a, 2011b).

The present study is an experimental investigation of the gas entrainment occurrence in water. The geometry of the experimental channel is close to that of Ezure *et al.*, 2008 and Kimura *et al.*, 2009. The main difference lies in the inlet conditions. To trigger different flow regimes, obstacles of various shapes are added (or not) at the end of the flat plate defining the inlet conditions.

The experimental set up and methods are described in section 2. The results are discussed in section 3. New results about gas entrainment introduced for the different inlet conditions are investigated. First, the required condition on the inlet and suction velocities for the occurrence of gas entrainment are studied and compared to previous literature. Second, the geometrical properties of surface swirls are characterized. Third, the projected areas of the air pumped via bubbles entrained through the suction nozzle are measured. This permits to describe and compare the behaviour of surface swirls and the quantity of air entrained according to different inlet configurations.

2. Experimental approach

2.1. Experimental setup

Experiments are performed using an open channel water flow. This channel is integrated in a close loop. A centrifugal pump mounted with an adjustable by-pass is used to generate different regulated flow rates. Flow rates are measured by electromagnetic flowmeters with an accuracy of $\pm 0.3\%$. Moreover, the temperature of the water is regulated at about 20°C using a heat exchanger.

The length and width of the test section are respectively 700mm and 108mm. The height of the free surface is 210mm. Figure 1 gives a sketch of the test section of the rig which is named BANGA.

To separate the main free surface flow from a stagnant water area, two vertical plates (300mm apart) are placed in

the middle of the channel so that inlet and outlet flows are limited to the half of the channel cross-section. To induce a secondary down-flow, some water is pumped through a suction nozzle. The diameter of the nozzle, noted D , is of 50mm and it is set at 100mm height, *i.e.* 110mm below the free surface. The origin of the Cartesian frame is set on the border of the vertical plate at the height of the suction nozzle. The x axis coincides with the horizontal channel flow direction, y and z axis are the horizontal and vertical directions, respectively.

The present experimental set up is relatively close to that of Ezure *et al.*, 2008 and Kimura *et al.*, 2009. One of originality of this work is the possibility to introduce obstacles. These obstacles are mounted at the end of the first vertical plate as illustrated by the square in Figure 1. They produce different inlet flow conditions amenable to impact on the structure of the turbulent shear flow so as to provoke different conditions for gas entrainment.

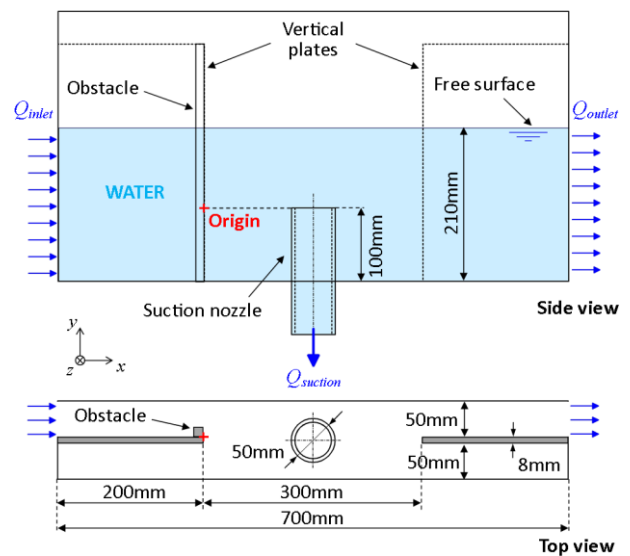

Figure 1. Test section of the rig BANGA: The top picture is the side view and the bottom one is the top view. The origin of the Cartesian frame is indicated with a cross. Q_{in} and Q_{out} denote the inlet and outlet flow rates, respectively.

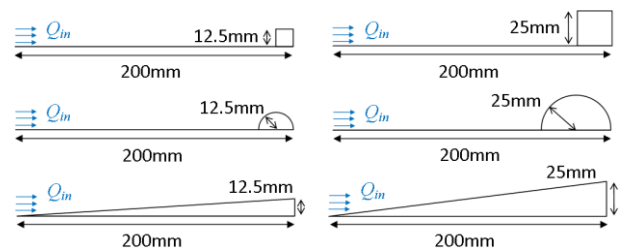

Figure 2. Illustration of the different configurations with obstacles.

Three geometries of obstacles are selected: square blocks (noted SB), half cylinders (noted HC) and ramps (noted RP). The square block and half cylinder are placed at the end of the vertical inlet Flat Plate (noted FP). The ramps are mounted along the flat plate with the highest part at its downstream end. Figure 2 illustrates these different

configurations with the obstacles. The height of the obstacles, noted h_{obs} , are either 12.5mm or 25mm.

2.2. Notations

The inlet and suction flow rates (in $m^3 h^{-1}$) are Q_{in} and Q_s respectively. The inlet and suction velocities are U_{in} and V_s respectively. U_{obs} is the velocity at the cross section perpendicular to the obstacles.

$$U_{in} = \frac{Q_{in}}{L_{in} h_{wat}}, \quad (1)$$

$$V_s = \frac{Q_s}{\pi D^2 / 4}, \quad (2)$$

$$U_{obs} = U_{in} \frac{L_{in}}{L_{in} - h_{obs}}, \quad (3)$$

where L_{in} is the width of the inlet channel (50mm) and h_{wat} is the water depth (210mm). For the flat plate configuration $h_{obs} = 0$.

Similarly to [Chang, 1979](#), the diameter D of the suction nozzle is chosen as the reference length scale to build dimensionless numbers. In particular, the dimensionless coordinates are noted with a * so that: $x^* = x/D$, $y^* = y/D$ and $z^* = z/D$.

The inlet and suction Reynolds number, respectively noted Re_{in} and Re_s , are defined as:

$$Re_{in} = \frac{U_{obs} D}{\nu}, \quad (4)$$

$$Re_s = \frac{V_s D}{\nu}. \quad (5)$$

where $\nu \cong 10^{-6} m^2 s^{-1}$ is the kinematic viscosity at 20°C.

In order to underline the competition between the free surface flow and the downward flow in gas entrainment and surface swirl occurrence, two parameters, κ and ξ are introduced:

$$\kappa = \frac{Re_{in}^2}{Re_s}. \quad (6)$$

$$\xi = \frac{Re_s^2}{Re_{in}}. \quad (7)$$

Later on κ is used to study phenomena where Re_{in} has a stronger influence than Re_s . In contrary, ξ is used to describe phenomena where Re_s as a stronger influence than Re_{in} .

2.3. Measurements and processing

Flow measurements rely mainly on Particle Image Velocimetry (PIV) measurements to provide details about the inlet conditions, *e.g.* velocity profiles, and on flow visualization and processing to observe and quantify the gas entrainment phenomenon.

Particle Image Velocimetry (PIV) measurements ([Raffel et al., 1998](#); [Rossi et al., 2013](#)) are performed using an *Evergreen*TM laser with double pulse laser sheets (thickness, wave length, duration and energy: 1mm, 532nm, 5ns, 120mJ). Double frames are recorded using a

*PowerView*TM Plus Charge Coupled Device (CCD) camera of spatial resolution 4872 x 3248 pixels. The time lags of the double frames vary from 1ms to 2.5ms according to the flow rates. PIV computations are performed using *Davis*TM software from *Lavis*TM. The final correlation windows are square windows of 48 pixels sides. An overlap of 50% is applied to build the velocity grid. Typical maximal displacements are about 10 pixels. The final instantaneous velocity fields are smoothed using a 3x3 mobile average.

The velocity fields are measured in the inlet area within horizontal and vertical planes. The vertical PIV planes are situated at $y = 32mm$ and $y = 37.5mm$ for 12.5mm size obstacles and the flat plate and for the 25mm side obstacles, respectively. These y values correspond to the middle position between the obstacles and the channel wall. The horizontal measurements are performed at $z = 50mm$ ($z^* = 1$) for all configurations. These latest measurements are performed from the side so as to avoid free surface deformations. To do so, the camera is set with an angle of 30° with the laser sheet. A calibration is applied to PIV frames to correct distortions using a reference grid and the ortho-rectification algorithm of *DAVIS*TM software.

Visualizations are performed in white backlighting with a *Stemmer Imaging*TM camera to observe surface swirl occurrence and gas entrainment phenomenon. Frames, with a spatial resolution of 2048 x 1088 pixels frames are acquired at 25Hz during 15min. The physical domain observed is 36cm long and 16 cm wide. It includes the free surface and the suction nozzle.

Image processing toolbox of *Matlab*TM is used to identify and quantify the occurrence of gas entrainment as follows:

1. The reference background, *i.e.* without gas entrainment, is subtracted to the original picture (Figure 3a) to improve the contrast. Such results are illustrated by Figure 3b.
2. The edges of the air areas are detected using the Canny method ([Canny, 1986](#)) evaluating the gray scale gradient. This step is illustrated in Figure 3c.
3. The edges are dilated to close opened contour. This step illustrated by Figure 3d.
4. The thick lines obtained are filled as illustrated in Figure 3e.
5. The filled shapes are eroded. This processing cleans the dilated border and removes the gray scale gradient of the free surface and the suction nozzle. This step is illustrated in Figure 3f.
6. Iso-countours are extracted (from the black and white image obtained) and are characterized as polygons so as to measure their geometrical characteristics. Resulting contours are illustrated in Figure 3g where they are superposed to the original picture.

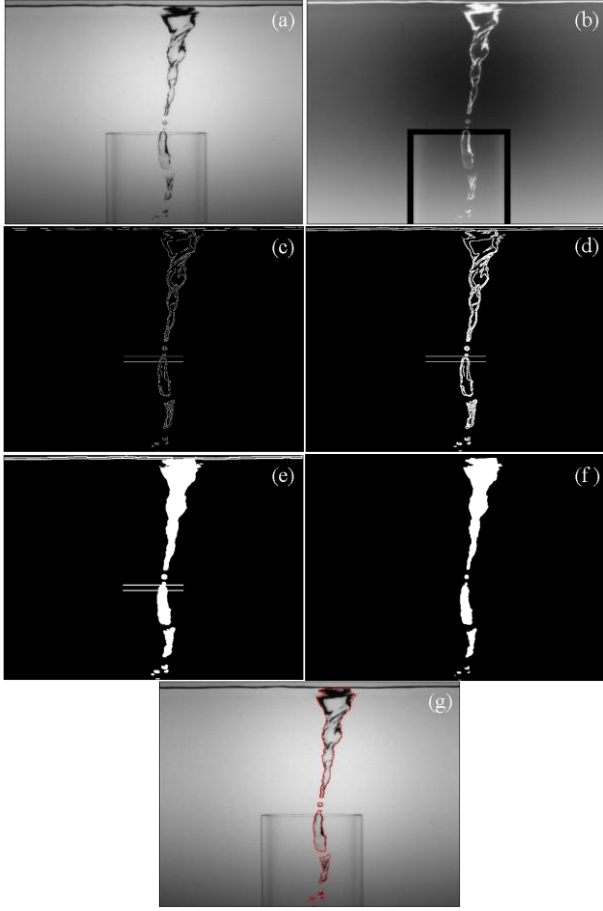

Figure 3. Illustration of the different image processing steps: (a) original image, (b) background subtraction, (c) edges detection, (d) edges dilatation, (e) filling closed contour, (f) erosion and (g) detected contours.

2.4. Flows explored

The Table 1 gives the flow rates, velocities and Reynolds numbers investigated.

Q_{in} m ³ /h	U_{in} m/s	Q_s m ³ /h	V_s m/s	Re_s	Re_{in}		
					obstacles h_{obs}		FP
					12.5mm	25mm	
1.9	0.05	1.9	0.27	13 500	3 333	5 000	2 500
3.8	0.1	2.8	0.4	20 000	6 667	10 000	5 000
		3.2	0.45	22 500

		5.7	0.8	40 000			
		7.1	1	50 000			
9.5	0.25	4.2	0.6	30 000	16 667	25 000	12 500
		5.7	0.8	40 000			
		7.1	1	50 000			

Table 1. Main flow parameters

Figure 4 provides 2D dimensionless mean velocity field, averaged over 250 velocity fields, in the inlet area, $\|\mathbf{u}\|/U_{in}$, for the 25mm side square block; $\|\mathbf{u}\|$ is the velocity amplitude. Figure 4a is measured at $y = 37.5\text{mm}$ and Figure 4b² is measured at $z = 50\text{mm}$. The two fields are in a good agreement. This highlights the reproducibility of the measurements since they are not made simultaneously. The black vectors indicate the direction of the flow. At the inlet, $x < -50\text{mm}$, the velocities are mainly parallel to the x -axis and their intensities are close to U_{in} . For $x > -25\text{mm}$, the local speed increases due to the contraction of the test section. For $x > 0$, a strong transverse velocity gradient occurs between the inlet and the stagnant flows (Figure 4b). This generates a shear flow in the wake of the obstacle.

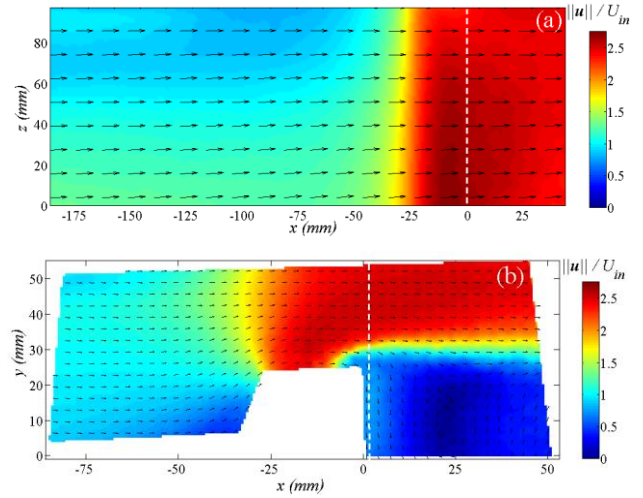

Figure 4. Dimensionless 2D temporal average, $\|\mathbf{u}\|/U_{in}$, in the inlet area at $y = 37.5\text{mm}$ (a) and $z = 50\text{mm}$ (b). Experiments with the 25mm side SB, $U_{in} = 0.25\text{m s}^{-1}$ and $V_s = 1\text{m s}^{-1}$. Black velocity vectors have a unit length to indicate the direction of the flow. White dashed lines represent the location of the profiles plotted in Figure 5.

Figure 5 gives the dimensionless velocity profiles extracted along $x = 0$. The confidence interval at 95% of these mean velocity profiles is about 1%.

In the vertical plane, the vertical component (Figure 5b) is clearly negligible compared to the axial component (Figure 5a). In the horizontal plane, values of the transverse component (Figure 5d) above $y = 25\text{mm}$ for 25mm side obstacles and $y = 12.5\text{mm}$ for 12.5mm side obstacles are close to zero. Under these y values, the transverse component is more important due to the wake of obstacle and recirculation flow. Moreover, the axial velocity jumps in Figure 5c correspond to the position of the shear flows between the inlet and the “stagnant” flow. As for the velocity fields, a good agreement appears between the vertical and the horizontal velocity profiles of the axial component (Figure 5a and Figure 5c). The amplitudes of the velocity profiles are ordered similarly for the two sizes

² Note that the boundaries of the velocity fields in Figure 4b are not straight because of the correction of the distortions.

of obstacles. The highest velocities are found for the inlet configuration with the 25mm radius half cylinder.

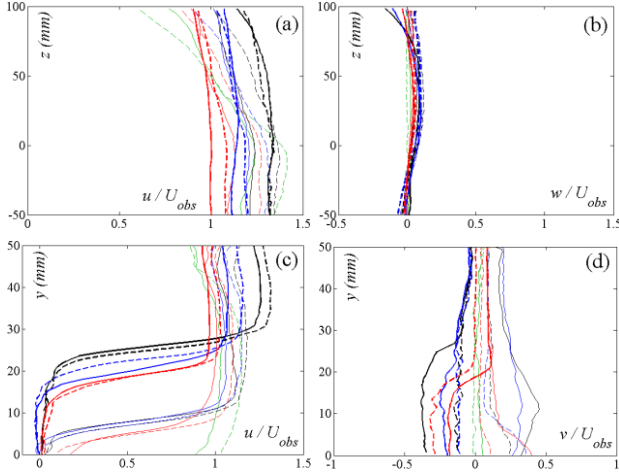

Figure 5. Dimensionless velocity profiles of (a) axial component u/U_{obs} and (b) vertical component w/U_{obs} are plotted at $x = 0\text{mm}$ in the vertical planes situated at $y = 32\text{mm}$ for the 12.5mm side obstacles and the FP, and $y = 37.5\text{mm}$ for the 25mm side obstacles (see Figure 4a). Dimensionless velocity profiles of (c) axial component u/U_{obs} and (d) transverse component v/U_{obs} are plotted few mm after $x = 0\text{mm}$ in the horizontal plane situated at $z = 50\text{mm}$ (see Figure 4b). The SB, HC, RP and FP are plotted in black, blue, red and green color, respectively (see online version of this article for color coded version of this figure). Thin lines are used for 12.5mm size obstacles and heavy lines are used for 25mm size obstacles. Dashed lines correspond to $U_{in} = 0.1\text{m s}^{-1}$, $V_s = 0.45\text{m s}^{-1}$ and solid lines correspond to $U_{in} = 0.25\text{m s}^{-1}$, $V_s = 1\text{m s}^{-1}$.

The turbulence intensity levels range from 5% to 11% according to the inlet configurations. Table 2 gives more details so as to highlight the role of the obstacles in generating turbulence.

U_{in} m/s	V_s m/s	SB	HC	RP	FP
		12.5mm size obstacles			
0.1	0.45	9	8.6	7.7	9.5
$U_{in} = 0.25\text{m/s}$ $V_s = 1\text{m/s}$		7.7	7.3	6.5	7.7
25mm size obstacles					
$U_{in} = 0.1\text{m/s}$ $V_s = 0.45\text{m/s}$		11.3	7.6	5.7	-
$U_{in} = 0.25\text{m/s}$ $V_s = 1\text{m/s}$		8.1	6.5	4.8	-

Table 2. Turbulent intensities in percent within the inlet region.

The velocities in the region of the suction nozzle are provided to complete the description of the experiments. Figure 6 gives the mean dimensionless velocity field, $\|\mathbf{u}\|/V_s$, for the 12.5mm side square block in the vertical plane at $y = 5\text{mm}$. This plane is close to the centre-axis of the suction nozzle. The flow inside the suction nozzle is not symmetric. This indicates that it is sensible to the mean horizontal flow in the channel. In particular, a wake effect appears in left part, for $-0.5 < x^* < 0$, when the flow goes into the suction nozzle.

Velocity profiles are plotted in Figure 7a for the axial component and in Figure 7b for the vertical component

along the white dashed line represented in Figure 6. These profiles highlight the non-symmetrical distribution of the flow inside the suction nozzle. The suction velocity profiles are close to a plateau for $-0.2 \leq x^* \leq 0.4$ with a ratio of the maximum of velocity to the mean velocity V_s varying between 1.2 and 1.4.

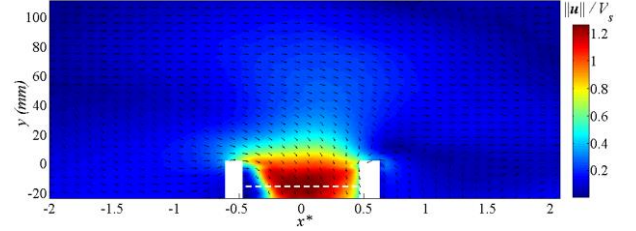

Figure 6. Dimensionless 2D temporal average, $\|\mathbf{u}\|/U_{in}$, in the vertical plane at $y = 5\text{mm}$, namely close to the center of the channel. Experiments with the 12.5mm side SB, $U_{in} = 0.25\text{m s}^{-1}$ and $V_s = 1\text{m s}^{-1}$. Black velocity vectors have a unit length to indicate the direction of the flow. White dashed lines represent the location of the profiles plotted in Figure 7.

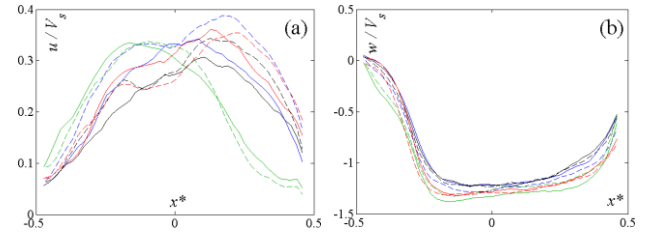

Figure 7. Dimensionless velocity profiles of (a) axial component u/V_s and (b) vertical component w/V_s are plotted at $z = -15\text{mm}$ and $y = 5\text{mm}$. The 12.5mm size SB, HC, RP and FP are plotted in black, blue, red and green color, respectively (see online version of this article for color coded version of this figure). Dashed lines correspond to $U_{in} = 0.1\text{m s}^{-1}$, $V_s = 0.45\text{m s}^{-1}$ and solid lines correspond to $U_{in} = 0.25\text{m s}^{-1}$, $V_s = 1\text{m s}^{-1}$.

3. Results and discussions

3.1. Gas entrainment mapping

Direct observations of the flow are performed to check if some gas is entrained or not. The onsets of gas entrainment are deduced from these observations.

The Figure 8 compares the present results with the ones obtained by Kimura et al., 2009 in the case of experiments with a flat plate. The results are close.

The Figure 9 provides gas entrainment mapping for the six obstacles according to the inlet velocity, U_{in} , and the suction velocity, V_s . When gas entrainment occurrences are observed the symbols are filled. The boundaries between the domains of gas entrainment and no gas entrainment are represented with red dashed lines. These thresholds change according to the shape and the size of obstacles. It is observed that the large obstacles trigger the occurrence of gas entrainment for lower suction velocities than for the small obstacles for a given U_{in} .

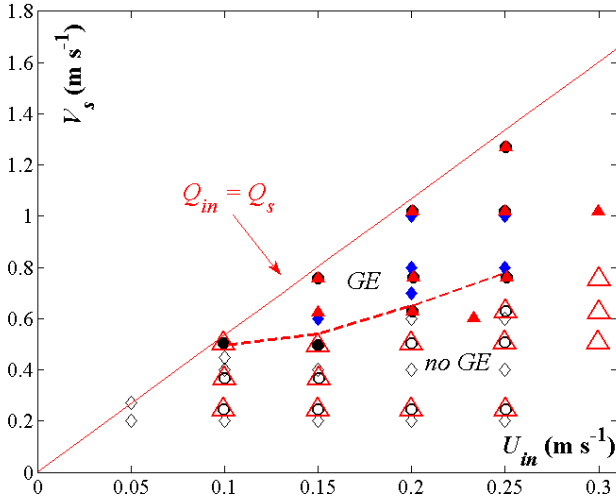

Figure 8. Gas entrainment mapping for the flat plate configuration. The present results are plotted with diamonds and the one from Kimura *et al.*, 2009 are plotted with circles for water experiments and with triangles for sodium experiments. Symbols are filled when there is gas entrainment. The dashed line gives the threshold of gas entrainment occurrence for the present study and the solid line is $Q_{in} = Q_s$.

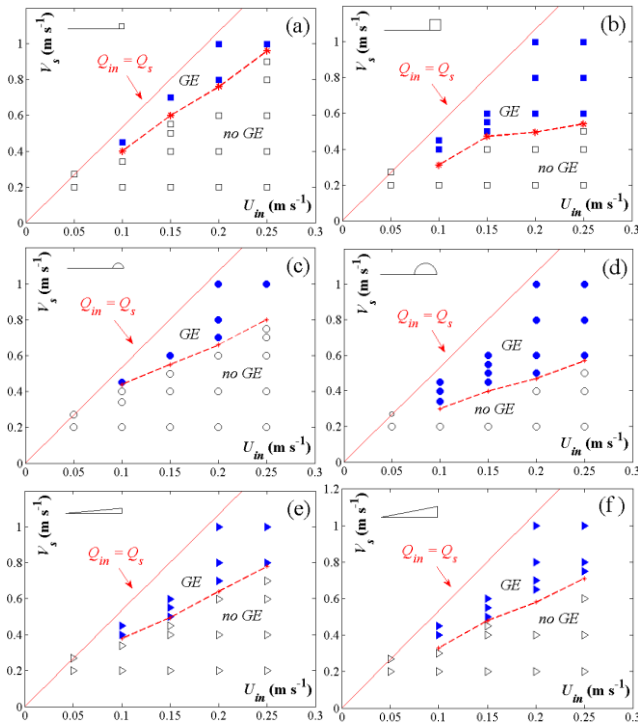

Figure 9. Gas entrainment mappings. SB of (a) 12.5mm and (b) 25mm side; HC of (c) 12.5mm and (d) 25mm radius; RP of (e) 12.5mm and (f) 25mm height. Symbols are filled when gas entrainment occurs. The solid line indicates $Q_{in} = Q_s$.

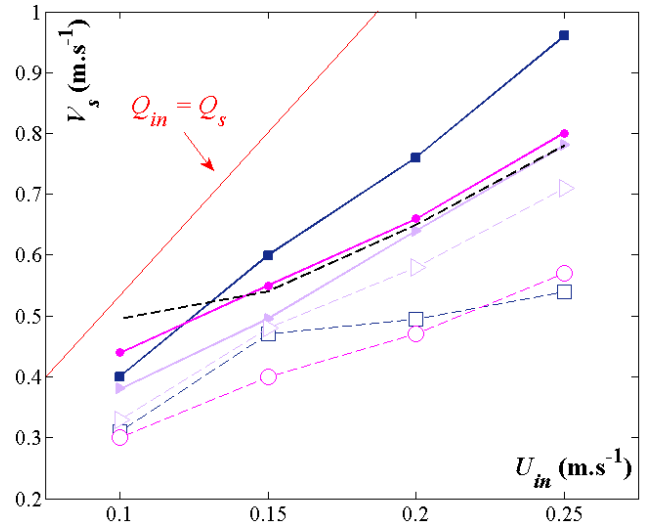

Figure 10. The thresholds of gas entrainment are plotted with solid lines and dashed lines for h_{obs} of 12.5mm and of 25mm respectively. SB, HC and Ramps cases are highlighted using squares, circles and triangles, respectively. The dashed line without symbol is the FP case.

The thresholds of gas entrainment are summarized in Figure 10 for all experimental configurations including the flat plate case. The cases can be ranked according to the V_s required to provoke gas entrainment for a given U_{in} . From the smallest to the highest V_s , this ranking is given in Table 3 along with the average ratio, noted \mathfrak{R}_s , of the threshold suction velocities to the one of the flat plate configuration.

Position	Obstacles	\mathfrak{R}_s
1	HC ($h_{obs} = 25mm$)	0.7
2	SB ($h_{obs} = 25mm$)	0.74
3	RP ($h_{obs} = 25mm$)	0.84
4	RP ($h_{obs} = 12.5mm$)	0.92
5	HC ($h_{obs} = 12.5mm$)	1
6	SB ($h_{obs} = 12.5mm$)	1.1

Table 3. Threshold of obstacles ranked according to the mean ratio, \mathfrak{R}_s , of the threshold suction velocity to the one of the flat plate case.

Increasing size of obstacles promotes gas entrainment and reverses the order of obstacles' thresholds in term of suction velocity. In the case of the 12.5mm size obstacles, gas entrainment occurs with a smaller value of V_s for the ramp than for the square block and the half cylinder. In the case of 25mm size obstacles, the ramp needs a higher value of V_s to induce gas entrainment than for the half cylinder and the square block. Moreover, small obstacles trigger gas entrainment for suction velocity close to the flat plate since values of \mathfrak{R}_s are close to 1. However, increasing size of obstacles triggers gas entrainment for smaller V_s than the flat plate configuration.

These results show that the occurrence of gas entrainment depends both, on the structure and on the intensity of the turbulent flow produced by the inlet conditions. The differences observed for different inlet

configurations may offer different test cases for MCFD codes.

3.2. Quantifications of gas entrainment and surface swirls properties

The two modes of gas entrainment observed are:

- air bubbles are pumped through the suction nozzle³,
- a continuous surface swirl reaches the suction nozzle.

Figure 11 illustrates these two observed modes for gas entrainment.

As the surface swirl is key to trigger gas entrainment, this subsection describes the geometrical properties of the surface swirl generated for the different flow configurations before discussing and quantifying the gas entrainment.

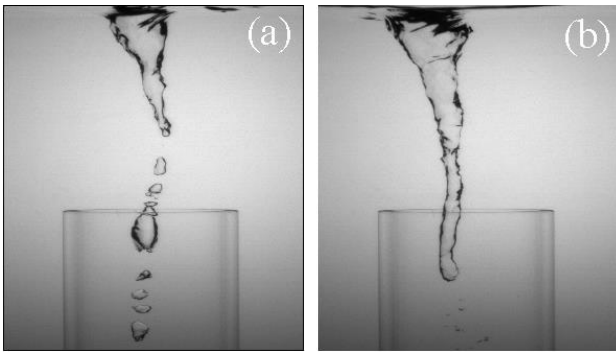

Figure 11. Illustration of gas entrainment through non-continuous (a) and continuous (b) surface swirls. Associated videos can be found on the online version of the paper.

3.2.1. Geometrical characteristics of the surface swirls

The Figure 12 gives three snapshots which illustrate the positions of the surface swirls varying the inlet configurations. The surface swirls positions are upstream or downstream the centre of the suction nozzle according to the inlet configurations.

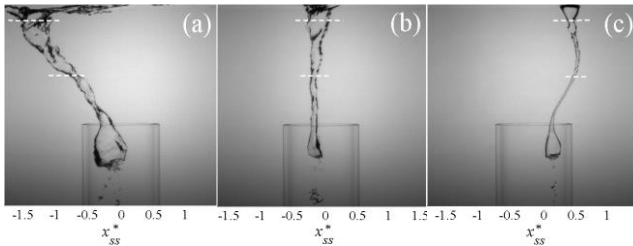

Figure 12. Illustration of continuous surface swirls for 25mm side SB (a), 12.5mm side SB (b) and PP (c) with $U_{in} = 0.2 \text{ m s}^{-1}$ and $V_s = 1 \text{ m s}^{-1}$. White dashed lines indicates planes $z^* = 2$ and $z^* = 1$. Corresponding videos are available online.

Using image processing, described in section 2.3. , the spatial positions of the surface swirls are measured at $z^* = 2$ (i.e. 10mm below the free surface level) and at

³ These bubbles are issued from the breaking of a surface swirls which results in a non-continuous surface swirl as illustrated in Figure 11a.

$z^* = 1$ as highlighted by the dashed white lines in Figure 12.

The dimensionless position of the center of the surface swirls is introduced as:

$$x_{ss}^* = (x_{ss} - x_{noz})/D, \quad (8)$$

where x_{ss} and x_{noz} denotes the x -axis positions of the centres of the surface swirls and the suction nozzle, respectively.

The probability distributions of x_{ss}^* at $z^* = 2$ are given in Figure 13 for different inlet configurations and flow intensities.

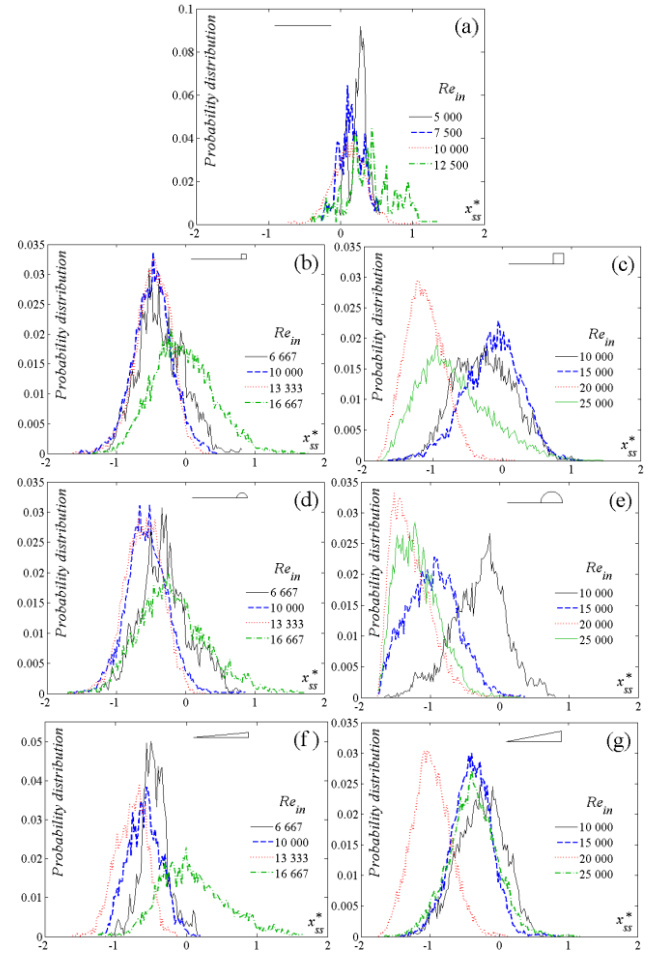

Figure 13. Probability distribution of the dimensionless positions of centre of the surface swirls, x_{ss}^* , at $z^* = 2$. (a) FP; (b) and (c) SB of sides 12.5mm and 25mm respectively; (d) and (e) HC of radius 12.5mm and 25mm respectively; (f) and (g) RP of height 12.5mm and 25mm respectively. Reynolds numbers, Re_{in} , are indicated in the figures' legend. Black solid lines and blue dashed lines correspond to $Re_s = 22500$ and 35000 , respectively. Red dotted lines and green dashed-dotted lines correspond to $Re_s = 50000$.

These distributions are not far from Gaussian distribution. The mean and the standard deviation of these positions' distribution varies with the obstacles, Re_{in} and Re_s . For the flat plate case (Figure 13a), the surface swirl tends to be downstream of the suction nozzle centre with $x_{ss}^* \geq 0$. For the cases with obstacles the surface swirl tends to be upstream of the suction nozzle with $x_{ss}^* \leq 0$. For the 12.5mm size obstacles, the highest probabilities are

observed around $x_{ss}^* \approx -0.5$ for $Re_{in} \leq 13333$. However, for higher Reynolds numbers, they are around $x_{ss}^* = 0$. For the 25mm size obstacles, the highest probabilities locations are more sensitive to Re_{in} values than for 12.5mm size obstacles.

To complement the probability distributions of Figure 13, the temporal average of, x_{ss}^* , noted $\overline{x_{ss}^*}$, and their standard deviations, σ/D , are given for $z^* = 2$ and $z^* = 1$ in Figure 14.

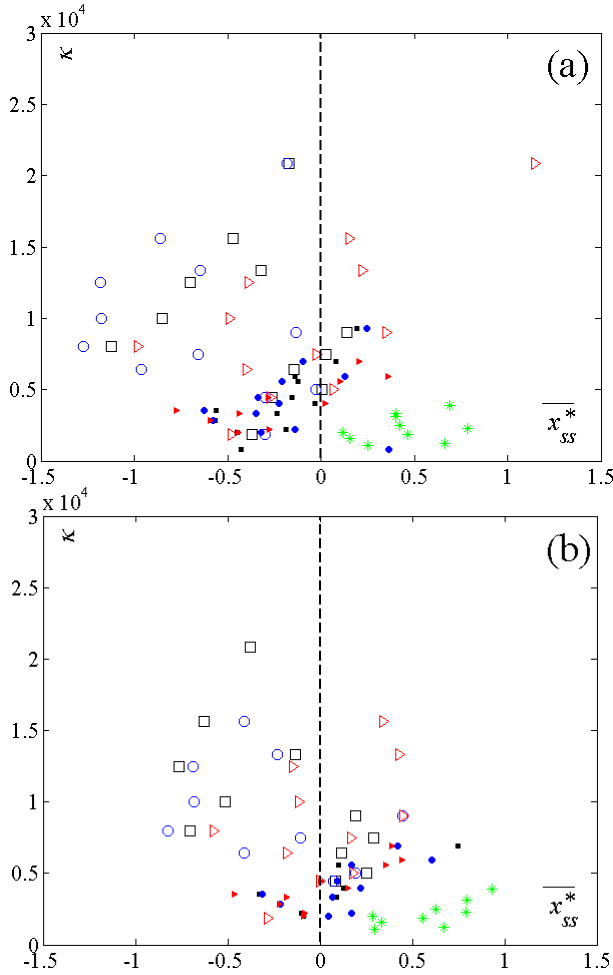

Figure 14. The parameter $\overline{x_{ss}^*}$ is plotted in abscissa and κ in ordinate at (a) $z^* = 2$ and (b) $z^* = 1$. The 12.5mm and 25mm size obstacles are respectively plotted with filled and empty symbols. Squares, circles, triangles and stars are used for SB, HC, RP and FP inlet configurations respectively.

The position $\overline{x_{ss}^*}$ is smaller for large obstacle than for small obstacle. For the inlet configurations with obstacles, $\overline{x_{ss}^*}$ tends to be negative for large obstacle at $z^* = 2$. The spreading of $\overline{x_{ss}^*}$ values is larger for $z^* = 2$ than for $z^* = 1$, in particular for the configuration with obstacles. This is due to the capture of the core of the surface swirls by the suction outlet as illustrated in Figure 12. It can be noted that for the configurations with small obstacles, $\overline{x_{ss}^*}$ tends to be negative for $z^* = 2$ and positive for $z^* = 1$. For the configuration without obstacles, $\overline{x_{ss}^*} > 0$ for $z^* = 1$ and $z^* = 2$.

Figure 15 gives the dimensionless standard deviation of x_{ss}^* , $\sigma^* = \sigma/D$, versus κ for $z^* = 2$ and $z^* = 1$. For the configurations with small obstacles and the flat plate, σ^* is found to increase with κ . For the configurations with the large obstacles, σ^* seems to fluctuate around a mean value $\langle \sigma^* \rangle$. They are provided in Table 4 at two positions. Values increase from the flat plate (0.23) to the square blocks (0.4) at $z^* = 2$ and are ranked with the same order between the two obstacles' size. Fluctuations are smaller for $z^* = 1$ than for $z^* = 2$.

These results highlight the fact the positions of the centres of the surface swirls strongly depend on the different flow configurations and their underlying turbulent structure.

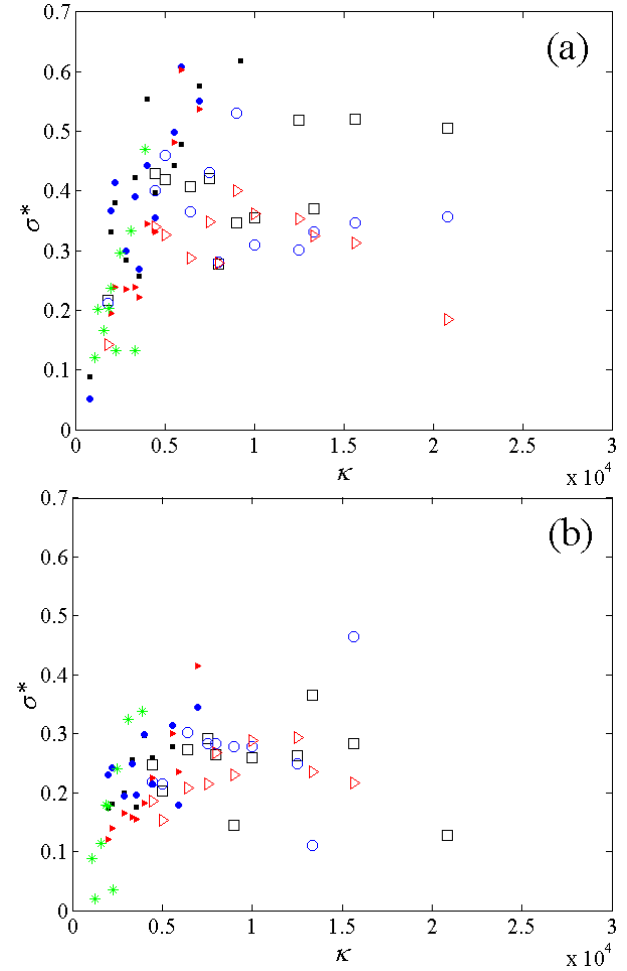

Figure 15. Plot of κ versus σ^* for $z^* = 2$ (a) and $z^* = 1$ (b). The configurations with 12.5mm and 25mm size obstacles are respectively plotted with filled and empty symbols. Squares, circles, triangles and stars are used for SB, HC, Ramps and FP cases respectively.

	12.5mm obstacles			25mm obstacles			FP
	SB	HC	RP	SB	HC	RP	
$z^* = 2$	0.4	0.35	0.34	0.4	0.36	0.3	0.23
$z^* = 1$	0.2	0.25	0.21	0.25	0.27	0.23	0.17

Table 4. $\langle \sigma^* \rangle$ at $z^* = 2$ and $z^* = 1$ for the configurations of Figure 15.

The thicknesses of the surface swirls are exported at $z^* = 2$ and $z^* = 1$ to build the Figure 16. It gives the average values of the dimensionless thicknesses, $L_{SS}^* = L_{SS}/D$, versus κ/κ_c . The parameter κ_c is a critical value of κ identified as the transition between two regimes for the growth of L_{SS}^* . Its value is about 5500.

The configurations with the large obstacles generate the largest diameters and the one with the flat plate the smallest.

The thickness L_{SS}^* increases like power laws of κ/κ_c , i.e. $L_{SS}^* \sim (\kappa/\kappa_c)^\beta$, when $\kappa/\kappa_c \leq 1$. The mean values of the exponents β are about 1 and 0.7 for $z^* = 2$ and $z^* = 1$ respectively. Fluctuation of the experimental points around these laws are typically about 8% at $z^* = 2$ and 16% at $z^* = 1$ which underline the good quality of this power law approximations. The exponents β are estimated using least square approximations. They are given in Table 5 for the different flow configurations along with the normalized standard deviations of the experimental points around these laws. For $\kappa/\kappa_c \geq 1$, L_{SS}^* does not increase significantly with κ/κ_c and it can be described as fluctuations around asymptotic values.

Here again, a notable difference appears between the flat plate and the obstacles at $z^* = 2$ since power β of the flat plate configuration is twice lower than the other configurations. However, at $z^* = 1$, the values of β are more homogenous between the different configurations.

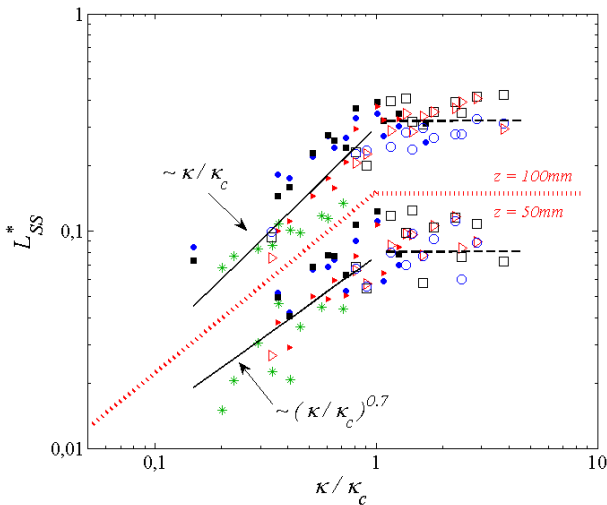

Figure 16. Dimensionless width of the surface swirls, L_{SS}^* , versus κ/κ_c with $\kappa_c \approx 5500$. Measurements at $z^* = 2$ and $z^* = 1$ are separated with a red dashed line. The inlet configurations with the 12.5mm and 25mm size obstacles are respectively plotted with filled and empty symbols. Squares, circles, triangles and stars are used for SB, HC, RP and FP cases respectively.

	12.5mm size obstacles			25mm size obstacles			FP
	SB	HC	RP	SB	HC	RP	
$z^* = 2$							
β	0.98	0.76	1.4	0.93	0.88	1.1	0.5
disp %	11.3	6.4	12.1	17	3.2	2.8	5.7
$z^* = 1$							

β	0.63	0.4	0.69	1.13	0.65	0.88	0.68
disp %	16.6	17.4	15.2	18.4	13.6	8	27

Table 5. Exponents of the power law approximation $L_{SS}^* \sim (\kappa/\kappa_c)^\beta$ and normalized standard deviations of the dispersion of the experimental points around these laws, noted *disp*, in percent.

3.2.2. Total area of the entrained gas

The total area, A_{gas} , of the air entrained through the suction nozzle is measured for the different inlet configurations.

Given the depth of the suction nozzle (100mm) and the range of suction velocities (see Table 1), the 25Hz frequency of the camera is sufficient to capture all bubbles during their crossing of the suction nozzle. However, the air bubbles can collapse and change shape between to frames. This makes bubble tracking methods difficult to implement. Likewise, one difficulty to estimate A_{gas} is to count all the bubbles and to not count twice the same bubbles in two different frames. Taking into account the area of bubbles included in a subdomain of constant size introduce a bias in the measurement. In particular, considering the entire suction nozzle overestimates A_{gas} since bubbles are counting twice.

When the bubbles are crossing down the suction nozzle, two opposite forces/phenomena are applied to bubbles: the downward suction flow and the buoyancy force. Moreover, the flow is accelerated at the entrance of the suction nozzle before being quasi-established further downstream. This is particularly important for large bubbles that, for example, can sometimes enter the suction nozzle and leave it from the top without being entrained by the suction flow. Nevertheless, these events are never observed when the bubbles reach the bottom part of the suction nozzle. In consequence, the areas of the air bubbles are counted over a measurement domain starting from the bottom of the suction nozzle with a depth depending on the flow.

Between two frames the displacement of the bubbles is about V_{bub}/f where V_{bub} is the speed of the bubble and f is the frequency of the camera. The domain of the suction nozzle where the area of bubbles is measured is adjusted to the flow conditions by roughly estimating V_{bub}/f . To do so the suction velocity and the terminal velocity of a spherical bubble of equivalent diameter are used. Without the buoyancy effect, bubbles are considered to have a displacement about $\gamma V_s/f$ between to frames. The parameter γ is an empirical coefficient which relates the fact that the velocity is not uniform within the suction nozzle (see Figure 6 and Figure 7). For each suction velocity, γ is fixed according to the measured velocity profiles to $\gamma = 1.25$. The suction velocity is corrected by the terminal velocity, noted V_{buoy} . For each bubble, the value of V_{buoy} is extracted from [Haberman and Morton, 1953](#) as a function of the bubble radius r_{bub} . The displacement considered for a bubble is then $(\gamma V_s - V_{buoy}(r_{bub}))/f$.

Hence, the area of a bubble, \mathcal{A}_{bub} , calculated in a frame is taken into account in A_{gas} calculation if the

coordinates of its centre, z_{bub} , is within the domain $z_{bub} \leq (\gamma V_s - V_{buoy}(r_{bub}))/f$. The Figure 17 illustrates this measurement domain.

The total area of entrained air in a recorded frame is defined by:

$$A_{gas} = \sum \mathcal{A}_{bub} \quad (9)$$

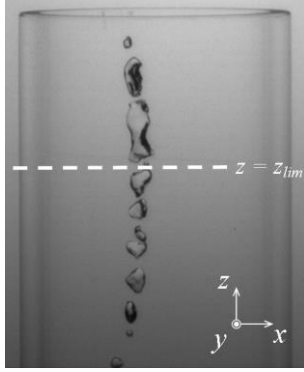

Figure 17. Illustration of the calculation of the entrained gas area through the suction nozzle. Bubbles' area is taking into account in A_{gas} when bubbles are placed under the white dashed line defined by $z = z_{lim}$ with $z_{lim} = (\gamma V_s - V_{buoy}(r_{bub}))/f$.

Figure 18 provides the dimensionless entrained gas area A_{gas}/D^2 versus ξ . The inlet configurations with obstacles entrain more air than the flat plate configuration. Among the cases with obstacles, the quantity of air pumped with large obstacles is greater than with small obstacles. In particular, for the two sizes, square blocks generate more entrained air than the half cylinder. The greater quantity of entrained air is induced by the large ramp whereas the smallest quantity of air is entrained by the small ramp, so that the ranking is inversed between the two sizes.

It can be observed that the large obstacles generate both larger surface swirls and higher quantity of entrained gas. Likewise, it is noticed that obstacles with a same size are ranked in the same way in term of threshold and entrained gas area.

Variation of dimensionless entrained gas area A_{gas}/D^2 is approximated as power law ξ^θ fitted to the experimental measurements with the least square method. Adding obstacles change significantly gas entrainment behaviour since the slope of the flat plate is very larger than cases with obstacles (see Table 6).

The total volume V_{gas} of entrained air is also estimated adding each measured bubble area to the power of 3/2: $V_{gas} = \sum_{i=1}^N \mathcal{A}_{bub}^{3/2}$, with N the number of bubbles. The associated flow rate, V_{gas}/t_{visu} , calculated on the visualisation time t_{visu} (15min), is plotted in Figure 19. As for the area A_{gas} , experimental set of data are fitted with a power law ξ^γ which exponents are provided in Table 7.

As expected, values of γ in Table 7 differs from $\theta^{3/2}$ (Table 6) since the number of bubbles changes with ξ and several size of bubbles are entrained.

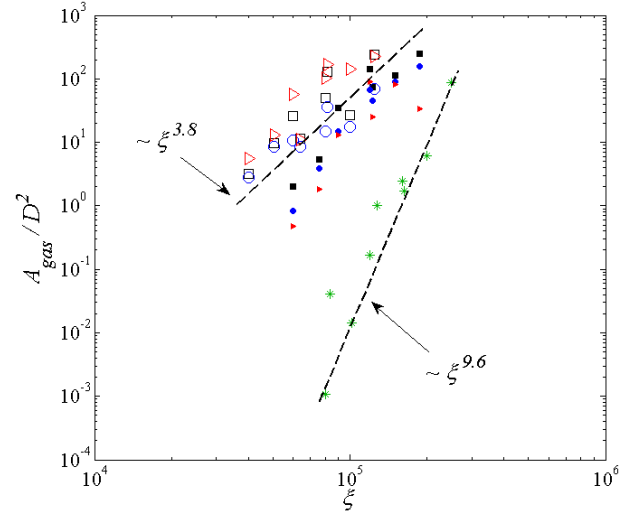

Figure 18. Dimensionless entrained gas area A_{gas}/D^2 versus ξ . The inlet configurations with 12.5mm and 25mm size obstacles are respectively plotted with filled and empty symbols. Squares, circles, triangles and stars are used for SB, HC, RP and FP cases respectively.

	12.5mm side obstacles			25mm side obstacles			FP

<i>disp</i>	37	33	57	85	36	45	49

Table 7. Exponents, γ , of the approximated power laws giving the volume V_{gas} of entrained gas in function of ξ , i.e. $V_{gas} \sim \xi^\gamma$ for the different inlet configurations. *disp* is the dispersion (in %) of the experimental points around these power laws.

4. Conclusion

The objective of the present study is to investigate gas entrainment through an experimental set up in water. Since wakes of obstacles are expected to be present in Sodium cooled fast nuclear reactor, obstacles, with different shapes and sizes, are added at the channel inlet to produce various inlet conditions. These new results reveal the dependence of the gas entrainment to the triggers generating different structures of the turbulent flows for similar bulk properties, i.e. flow rates. These results complement the existing knowledge issued from the experiments using the flat plate configuration and open new perspectives.

The measurement of the suction velocity threshold required to provoke gas entrainment show that small obstacles behave similarly to the standard shear flow generated using the flat plate configuration. The configurations using the large obstacles tend to provoke gas entrainment for lower values of the suction velocity than the other configurations. Moreover, the ranked of the obstacles in terms of suction velocity required to entrain gas (at a given inlet velocity) is inversed between the two sizes of obstacles.

To study the details of the flow physical mechanisms, the occurrences and behaviour of the surface swirls are described. Moreover, in the context of nuclear safety for RNR-Na, it is important to quantify the volume of argon entrained in sodium through the heat exchanger. Then, an imaging processing tool is developed to detect the contour of surface swirl and entrained bubbles from shadowgraphy.

The different inlet configurations influence the width and the position of surface swirls. To our knowledge, the quantification of geometrical properties of the surface is a new result in the study of gas entrainment in open channel flow experiments. For the configuration with obstacles, they are larger and situated upstream from the suction nozzle. For the flat plate configuration the surface swirls are downstream the suction nozzle. It is found that for all cases, their widths vary with a power law of κ . Surface swirl width increases with κ for small obstacles and the flat plate until a critical value of κ at 5500. From this value, it fluctuates around an asymptotic value for large obstacles.

The quantity of entrained gas is also estimated using a method taking into account suction velocity and buoyancy effect on bubbles. Here again, a power law of the entrained gas area was found. It implies the dimensionless parameter ξ where the role of Reynolds numbers is inversed compared to the surface swirl width law. The flat plate

differs clearly from the cases with obstacles which are assembled around a same power. Number of bubbles change with values of ξ and several sizes of bubbles are entrained through the suction nozzle.

To conclude, adding obstacles in the channel inlet area modifies significantly the gas entrainment and the surface swirl behaviour. In addition to provide new insights, it is expected that the detailed study of the configurations presented in this manuscript should offer interesting test cases for numerical codes validation.
