13 cyclopeptides, phosphopeptides isomers, retention mechanisms, ESI-MS.

14 Abstract

15 Peptides are efficient models used in different fields such as toxicology to study the interactions of
16 several contaminants at the molecular scale, requiring the development of bio-analytical strategies. In
17 this context, Hydrophilic interaction liquid chromatography (HILIC) coupled to electrospray
18 ionization mass spectrometry (ESI-MS) was used to separate synthetic multiphosphorylated
19 cyclopeptides and their positional isomers at physiological pH. We assessed (i) the selectivity of
20 eleven HILIC columns, from different manufacturers and packed with diverse polar sorbents, and (ii)
21 the effect of mobile phase composition on the separation selectivity. The best selectivity and baseline
22 resolution were achieved with the columns grafted by neutral sorbents amide and diol. Furthermore,
23 we investigated the HILIC retention mechanism of these peptides by examining the effect of the
24 number of phosphorylated residues in the peptide scaffold on their retention. The peptide behavior
25 followed the classical hydrophilic partitioning mechanism exclusively on amide and diol column. This
26 trend was not fully respected on bare and hybrid silica due to the attractive/repulsive interactions of
27 the deprotonated surface silanol groups with the Arginine or Glutamate residues in the peptide scaffold
28 according to the peptide sequence. The position of the phosphorylated amino acid in the peptide
29 backbone also showed to have an impact on the retention, making possible the separation of positional
30 isomers of these multiphosphorylated cyclic peptides using HILIC.

31 Introduction

32 Peptides are efficient models to study metal-protein binding sites [1,2] and some of their derivatives
33 have been proposed as specific metal chelators in detoxification applications [3,4] or as models of
34 enzyme activity [5]. Peptides with sequences found in albumin [6], osteopontin [7] and calcium
35 binding calmodulin [8] have been used to help identifying uranium (U) chelation sites in these proteins
36 and to evaluate their affinity towards this cation, using spectroscopic techniques such as fluorescence
37 spectroscopy, isothermal titration calorimetry (ITC), extended X-ray absorption fine structure
38 (EXAFS) and circular dichroism. Uranyl ion displays a specific geometry that promotes coordination
39 of ligands in the equatorial plane perpendicular to the O-U-O axis. In this context, pre-organized
40 cyclodecapeptides designed specifically to coordinate U have been synthesized to mimic the so far
41 unknown uranyl ion binding sites in phosphate-rich proteins, such as osteopontin [9]. In the
42 cyclodecapeptides shown in Figure 1, the four amino acid side chains at positions 1, 3, 6, and 8 are
43 pre-oriented in the “upper face” of the peptide scaffold to efficiently coordinate uranyl in its equatorial
44 plane. Those amino acids were initially four glutamic acids (Glu) in pS0 [10] that were progressively
45 replaced by phosphoserine (pSer) to obtain four pSer residues in pS1368. Peptides are named
46 according to the number and position of the pSer residues [11–13].

47 In view of developing a dedicated analytical method by chromatography coupled to mass spectrometry
48 to determine an affinity scale of these peptides towards uranium based on the separation of the uranyl-
49 peptide complexes at physiological pH (~ 7), the prior investigation of the separation conditions and
50 chromatographic behavior of these kind of peptides is crucial.

51 In the field of phosphoproteomics, various chromatographic approaches have been applied to separate
52 phosphopeptides from their non-phosphorylated counterparts in complex samples such as proteomic
53 digests. Dedicated methods, mainly based on multidimensional chromatography often involving ion-
54 exchange chromatography combined with reversed-phase chromatography (RPLC) have been set up,
55 and generally in acidic conditions [14,15]. Hydrophilic interaction liquid chromatography (HILIC) is
56 dedicated to the separation of polar and hydrophilic molecules [16]. It combines polar stationary
57 phases and hydro-organic mobile phases rich in organic modifier containing a volatile salt, providing

58 suitable conditions for ESIMS detection [17]. The analytes are retained according to their polarity and
59 hydrophilicity through liquid-liquid partition between the mobile phase and a semi-immobilized water
60 layer on the surface of the polar stationary phase, being the main retention mechanism [18].
61 Furthermore, secondary interactions such as hydrogen-bonding, dipole-dipole and electrostatic
62 interactions generally contribute also to the retention at different degrees. Because of these features,
63 HILIC has been more and more used these last decades to separate amino acids, peptides, metabolites
64 and proteins [19] and has gained popularity in phosphoproteomics [20]. Using this separation mode,
65 various polar stationary phases, mainly amide [21–24], zwitterionic [25,26], bare silica [21,22] and
66 less frequently amino [23,27] and diol [27,28], have been used in one dimension or hyphenated with
67 RPLC in second dimension [29,30] in studies involving unphosphorylated or multiphosphorylated
68 linear peptides under acidic conditions. Concerning positional isomers, to our knowledge, only one
69 study reports the separation of the positional isomers of linear multiphosphorylated peptides from
70 protein digests, using aminopropyl HILIC stationary phase under strong acidic conditions (pH 2) [27].
71 The aim of this work was to set up the conditions to separate at physiological pH, synthetic pre-
72 organized multiphosphorylated cyclodecapeptides including positional isomers (see Figure 1) using
73 HILIC coupled to ESI-MS. In general, the peptide separations are carried out in acidic conditions but
74 in our study, physiological pH is a key-parameter to reflect biological conditions relevant in
75 toxicology, that are required for the following steps aiming at characterizing uranium interactions with
76 these peptides. The selectivity of eleven polar stationary phases from different manufacturers was
77 evaluated using different mobile phase compositions. In addition, the retention mechanisms of the
78 peptides on the different columns were discussed, as well as the impact of the nature and the position
79 of the amino acids in the sequence on the peptide retention.

80 1. Experimental part

81 1.1. Chemicals

82 Acetonitrile (ACN, CH₃CN, LC-MS grade) was supplied by VWR prolabo (Briare le canal, France).
83 Ammonium acetate (NH₄O₂CCH₃) and toluene (C₆H₅CH₃, purity > 99.7 %) were purchased from
84 Sigma Aldrich (Saint Quentin Fallavier, France). Ultrapure water (18.2 MΩ cm) was obtained from
85 Milli-Q purification system (Merck millipore, Guyancourt - France).

86 1.2. Peptides

87 The peptides were synthesized, characterized using ESI-MS and circular dichroism and supplied by the
88 CIBEST team at SyMMES (Univ. Grenoble Alpes, CEA, CNRS, IRIG, 38 000 Grenoble - France)
89 following the procedures described elsewhere [10–13]. Table 1 summarizes nomenclature, amino acid
90 sequence, molecular mass and the maximum charge at pH 7.4 for each peptide.

91 Table 1: nomenclature, amino acid sequence, molecular mass and maximum charge at pH 7.4 for each peptide.

Peptides	Sequence (X ₁ X ₂ X ₃ X ₄ X ₅ X ₆ X ₇ X ₈ X ₉ X ₁₀)	Molecular mass (g mol ⁻¹)	Maximum charge at pH 7.4
pS0	c(ER EPGE WEPG)	1166.5	-3
pS1	c(pS RE PGEW EPG)	1204.5	-4
pS8	c(ER EPGE W pSPG)	1204.5	-4
pS16	c(pS RE PGpSW EPG)	1242.4	-5
pS18	c(pS RE PGEWpSPG)	1242.4	-5

pS1368	c(pS E pSPGpSWpSPG)	1291.3	-9

92 X is the letter code of amino acids. pS stands for phosphorylated serine residues (pSer)

93 1.3. Preparation of peptide stock solutions and samples

94 The peptide stock solutions were prepared by dissolving the adequate amount of the targeted peptide
95 powder in 20 mmol L⁻¹ NH₄O₂CCH₃ (pH ~ 7) to reach a concentration between 2 and 4 mmol L⁻¹. An
96 intermediate solution containing around 2.5 x 10⁻⁴ mol L⁻¹ pS0, pS1/8, pS16/18 and around 5 x 10⁻⁴
97 mol L⁻¹ pS168 and pS1368 was prepared by mixing the adequate volume of the peptide stock solutions

98 and adding further the appropriate volume of 20 mmol L⁻¹ NH₄O₂CCH₃. The working samples were
99 obtained by diluting the intermediate solution in the reference mobile phase (70/30 ACN/H₂O v/v + 20
100 mmol L⁻¹ NH₄CH₄CO₂) to reach final peptide concentrations of 5 x 10⁻⁵ mol L⁻¹ for pS0, pS1/8 and
101 pS16/18. , and 10⁻⁴ mol L⁻¹ pS168 and pS1368

102 1.4. Instrumentation

103 Experiments were carried out using an ultimate 3000 UHPLC⁺ Dionex/ThermoFisher scientific
104 (Courtaboeuf, France), which consists of a degasser, a dual RS pump, an RS autosampler, a column
105 compartment and an RS diode array detector. A triple quadrupole TSQ Quantum UltraTM mass
106 spectrometer (Thermo Fisher scientific, San Diego CA, USA) equipped with an H-ESI II ionization
107 probe was coupled to the chromatographic system. All mass spectra were recorded in negative
108 ionization mode with the following parameters: spray voltage -3.5 kV, temperature of the probe 120
109 °C and temperature of the capillary 360 °C. Mass spectra were acquired in full scan (*m/z* 400-1500)
110 and in single ion monitoring (SIM) by selecting the *m/z* ratio associated to each peptide (spectral
111 width: ± 0.5 *m/z*).

112 1.5. Chromatographic conditions

113 The peptide separations were performed with eleven columns (see Table 2) in isocratic elution.
114 Targeted mobile phase composition was obtained by online mixing of solvent A (60/40 ACN/H₂O v/v
115 + 20 mmol L⁻¹ NH₄O₂CCH₃) and solvent B (80/20 ACN/H₂O v/v + 20 mmol L⁻¹ NH₄O₂CCH₃) in the
116 adequate proportions. The flow rate was 300 μL min⁻¹ and the injection volume was 3 μL except for
117 YMC-Triart Diol column, for which it was 1 μL.

118
119

Table 2 : Column specifications: name, manufacturer, base material, carbon load (%), surface area (m² g⁻¹), and column dimensions.

120

121 Peptide retention factor k was calculated for each column in accordance with the following equation

122 (1):

$$123 \quad k = \frac{(t_R - t_0)}{t_0} \text{ (Equation 1)}$$

124 Where t_R is the retention time (min) of peptides, determined by HILIC-ESIMS, t_0 is the void time of

125 unretained marker, toluene (10^{-4} mol L⁻¹, $V_{inj} = 1 \mu\text{L}$), determined by HILIC-UV/VIS at 254 nm.

126 Selectivity and resolution factors, α and R_s respectively, were calculated based on equations 2 and 3:

$$127 \quad \alpha = \frac{k_2}{k_1} \text{ (Equation 2)}$$

$$128 \quad R_s = 1.18 \times \frac{t_{R2} - t_{R1}}{W_{0.5h1} + W_{0.5h2}} \text{ (Equation 3)}$$

129 Being analyte 2 more retained than analyte 1. $W_{0.5}$ corresponds to full width half-maximum of each
130 peak.

131 Asymmetry factor As was calculated for every separation using all the tested columns at the mobile
132 phase composition 70/30 ACN/H₂O + 20 mmol L⁻¹ NH₄O₂CCH₃ according to the following equation
133 (4):

$$134 \quad As = b/a \text{ (Equation 4)}$$

135 Where a is the width at the left half of the peak at 10% peak height and b is width at the right half of
136 the peak width at 10% peak height.

137 2. Results and discussion

138 2.1. *Selectivity of various polar stationary phases*

139 The separation of peptides using the eleven columns was first assayed with a reference mobile phase
140 consisting of ACN/H₂O 70/30 v/v + 20 mmol L⁻¹ NH₄O₂CCH₃ [31] at physiological pH. The
141 corresponding elution profiles (Figure 2) and the chromatographic parameters such as k' , A_s , α and R_s
142 (Table 3) reflect the different selectivity of the tested columns for separating the cyclopeptides in these
143 conditions. With bioZen glycan, no elution of peptides was observed even using different mobile
144 phase compositions. Therefore, this column is not suitable and was dropped out from the study.

145
146Table 3: Chromatographic parameters (k' , As , α and Rs) calculated for the separation of the peptides with stationary phases grafted by different polar functional groups, using a mobile phase composition of 70/30 ACN/H₂O + 20 mmol L⁻¹ NH₄O₂CCH₃.

148 Bare silica columns such as Luna Silica, YMC-Pack SIL and Hypersil GOLD Silica display a highly
149 polar and negatively charged stationary phase at pH 7 due to deprotonated surface silanol groups.
150 Because of this high polarity, the highest retention factors of all the peptides were obtained with the
151 first two columns among all the tested ones with k' reaching for example 45.8 and 31.9 for
152 monophosphorylated pS1 on Luna Silica and YMC-Pack SIL (see Table 3). It must be noticed that
153 retention is significantly lower for the Hypersil GOLD Silica, with $k'=12.3$ for pS1. The retention of
154 the negatively charged peptides displaying the same charge as the stationary phase reflects that the
155 main retention mechanism-taking place is hydrophilic partitioning with respect to electrostatic
156 repulsions, that solely would lead to decreased or no retention of analytes. The retention of analytes
157 displaying the same charge as the stationary phase is one of the HILIC features compared to ion
158 exchange chromatography [32].

159 In the case of the highly retentive Luna Silica, only broad peaks were observed for pS0, pS1 and pS8,
160 while none of the remaining multiphosphorylated peptides was observed using this mobile phase
161 composition. In the same conditions, all the peptides were eluted with the YMC-Pack SIL and
162 Hypersil GOLD Silica columns. This difference is attributed to the surface area of the columns,
163 varying as follows: Hypersil GOLD Silica < YMC-Pack SIL < Luna Silica (Table 2) and leading to
164 increasing retention of peptides accordingly. Using YMC-Pack SIL and Hypersil GOLD Silica, pS16
165 was the most retained peptide with $k' = 65.7$ and 18.8, respectively. Overall, a good separation of the
166 pS8-pS1 positional isomers was achieved with the three columns with selectivity factors of 2.4 for
167 Luna Silica and YMC-Pack SIL and 2.8 for Hypersil Gold Silica.

168 Hybrid silica Acquity UPLC BEH HILIC and YMC-Triart SIL columns contain non-grafted stationary
169 phases, made of supports with different hybrid technologies. Bridged ethylene hybrid (BEH) supports
170 consist of ethylene bridges embedded within the silica matrix that coat nearly one-third of the surface
171 silanols [33]. YMC-Tiart SIL is based on hybrid particles with multi-layered organic/inorganic silica
172 [34]. Hybrid supports provide stationary phases with lower deprotonated surface silanol groups and
173 decreased polarity compared to bare silica columns, leading to lower peptide retention factors as can
174 be seen in Figure 2 and Table 3. For example, pS1 retention factor is three times lower with YMC-
175 Triart SIL ($k' = 11.8$) than with YMC-Pack SIL ($k' = 31.9$). As observed with bare silica columns, the

176 peptides were more retained on the column exhibiting the higher surface area that is the YMC-Triart
177 SIL with respect to the Acquity UPLC BEH HILIC (Table 2) and pS16 was eluted with the highest
178 retention factor with both hybrid silica columns.

179 The remaining columns are based on bare or hybrid silica supports, grafted with different functional
180 groups such as amide, diol and zwitterionic.

181 Acquity UPLC BEH amide is based on hybrid silica support, grafted with neutral amide groups
182 through an alkyl spacer. As neutral stationary phase, analyte retention is driven by hydrophilic
183 partitioning as main mechanism and hydrogen bonding also contribute to the retention owing to the
184 hydrogen donor and acceptor ability of the amide group. Accordingly, the retention factors of the
185 peptides increased with respect to the number of pSer residues in the peptides scaffold in agreement
186 with their increasing polarity and hydrophilicity (Figure 2 and Table 3). Amide stationary phase
187 displayed high separation selectivity and baseline resolution for separating these cyclic peptides,
188 including their positional isomers (R_s pS8-pS1 = 2.2 and R_s pS18-pS16 = 1.8).

189 Acclaim HILIC-10 is based on bare silica support, grafted with a proprietary hydrophilic functional
190 group. It showed weak retention of the peptides leading to co-elution of most of them and a poor
191 baseline resolution ($R_s < 1.5$ as shown in Table 3). This reflects the insufficient polarity of the
192 functional group for separating these peptides under the selected conditions.

193 ZIC-pHILIC is a zwitterionic column, made of a polymer material grafted with a sufoalkylbetaine
194 chain that contains both negatively charged sulfonic acid and positively charged quaternary
195 ammonium separated by a short alkyl spacer. As the two oppositely charged groups are present in
196 equimolar ratio, the zwitterionic function is globally neutral. Sulfoalkylbetaine columns strongly
197 adsorb water, therefore hydrophilic partitioning is the main retention mechanism of the analytes. but
198 weak electrostatic interactions contribute to the retention of charged analytes as well as hydrogen
199 bonding [17]. Taking into account these features, the retention of the peptides increased in connection
200 with the number of pSer groups, even though in this mobile phase composition peaks are poorly
201 resolved ($R_s < 1.5$. except for pS16-pS1368 $R_s = 2.8$. see Table 3) and the tri- and
202 tetraphosphorylated peptides were co-eluted (Figure 2).

203 YMC-Triart Diol and Inertsil Diol columns are respectively based on hybrid and pure silica supports,
204 grafted with neutral dihydroxypropyl groups through a spacer. The separation is based on hydrophilic
205 partitioning as major retention mechanism, in combination with hydrogen bond interactions through the
206 OH group. Using the reference mobile phase, the peptides were weakly retained and almost co-eluted,
207 which is explained by the low polarity and hydrophilicity of diol stationary phases. The retention
208 factors are slightly different with both columns despite being grafted with the same functional group.
209 For example k'_{pSI} with YMC-Triart Diol ($k' = 4.5$) is almost twice the observed with Inertsil Diol ($k' =$
210 2.5). It is important to mention that despite having a hydroxy group on both diol columns, they display
211 differences in the carbon chain length, which is higher for Inertsil Diol. In addition, this latter has an
212 ether group in its chain, which is not present with YMC-Triart Diol (see Table 2). This illustrates that
213 columns categorized as same stationary phase are different between manufacturers in the architecture
214 of the functional group, the grafting rates and the technology of the material support.

215 The first screening of various columns for separating multiphosphorylated cyclic peptides using a
216 fixed mobile phase composition showed diverse selectivity according to the chemical group bonded to
217 the stationary phase. Acquity UPLC BEH amide showed to be suitable for the separation of the
218 peptides. These latter displayed a different chromatographic behavior with the remaining columns and
219 in some cases, we obtained a good separation of the positional isomers, making interesting a further
220 investigation of the effect of mobile phase composition on the separation selectivity mechanism of
221 these phosphorylated cyclopeptides and of their HILIC retention mechanism.

222 2.2. *Effect of mobile phase composition*

223 The mobile phase's elution force is another parameter influencing the separation selectivity in HILIC
224 and is highly related to organic content of the mobile phase. By way of example. Figure 3 shows the
225 chromatographic behavior (Figure 3A) and the retention factors of the peptides (Figure 3B) in function
226 of the mobile phase's organic content for columns of increasing polarity: Acclaim HILIC-10, diol
227 (YMC-Triart Diol). Zwitterionic (ZIC-pHILIC) and bare silica (YMC-Pack SIL). In all cases, the salt
228 concentration was kept at 20 mmol L^{-1} .

229 As previously observed, 70% ACN in the mobile phase induced unacceptable retention factors with
230 the more polar bare silica columns. We therefore assessed the effect of higher mobile phase's elution

231 force for this class of stationary phases by decreasing the proportion of ACN. This latter was
232 decreased up to 40 % with the highly retentive Luna Silica column, but pS168 and pS1368 were still
233 not eluted and pS18 and pS16 were eluted near the void time (data not shown), rendering this column
234 not suitable for the rest of the study. For YMC-Pack SIL, the peptide retention factors of all the
235 peptides decreased with the ACN percentage as expected (Figure 3A and B). It must however be
236 noticed that elution order changed between pS168 and pS1368 and their neighboring peptides when
237 the mobile phase's elution force was modified (Figure 3B). The same behavior was observed on
238 Hypersil Gold Silica but only for pS1368 (see Table 3 and Supporting Information).

239 For the less polar remaining columns, the elution force was decreased by increasing the mobile phase
240 organic content, promoting the retention of the peptides in all cases. With the Acclaim HILIC-10, the
241 ACN content was increased up to 77%, but the selectivity was still insufficient (Figure 3A) and the
242 separation of the peptides was not achieved. A composition of 80 % ACN did not improve the
243 separation performance either and yielded retention factors up to 28.5 with very wide peaks.

244 Concerning the YMC-Triart Diol, the ACN content was increased up to 75 % giving a good separation
245 selectivity ($1.1 < \alpha < 1.5$) and baseline resolution ($R_s > 1.5$) except for the pS168/pS16 ($R_{S_{pS168-pS16}} =$
246 0.9) and pS1/pS18 ($R_{S_{pS1-pS18}} = 1.4$) pairs (See Supporting Information). A change in the elution order
247 was also observed between pS168 and pS1368 and their neighboring peptides at 72% and 74% ACN
248 respectively (Figure 3A and B). We could suggest that a change in the retention mechanism occurred
249 and that secondary interactions of the peptides with the stationary phase through hydrogen bonding
250 took more important part. For Inertsil Diol, increasing the ACN content up to 75% improved the
251 separation selectivity but was still insufficient due to the wide peaks obtained at this percentage (see
252 Supporting Information). Contrary to YMC-Triart Diol, we observed no change in the elution order of
253 the peptides while modifying the mobile phase composition. For ZIC-pHILIC column, the peptides
254 were eluted in two groups whatever the ACN content. The first one includes peptides with 0, 1 and 2
255 pSer residues and their positional isomers, which were separated with a good selectivity and baseline
256 resolution at 72% ACN ($1.5 < R_s < 2.4$ and $\alpha > 1$). The second one includes tri- and
257 tetraphosphorylated peptides pS168 and pS1368, which were co-eluted at all the mobile phase
258 compositions. It must be noticed that pS1368 displayed a very large peak at 74% and 76% ACN,

259 making difficult the precise identification of the apex. With hybrid silica columns (see Table 1), the
260 ACN amount was increased up to 74 % which did not improve the separation performance and lead to
261 very large peaks and co-elution of some of the peptides (data not shown).

262 Overall, the mobile phase modification induced in some cases an inversion of the elution order only
263 between the tri- and tetra- phosphorylated peptides pS168 and pS1368 and their neighboring peptides
264 respectively. This result reflects that pS168 and pS1368 are more sensitive to the mobile phase
265 polarity than the other peptides.

266 2.3. *HILIC behavior of the multiphosphorylated cyclopeptides*

267 It is commonly known that in HILIC, retention increases with analyte polarity [17]. Therefore, higher
268 retention of the peptides is expected by increasing the number of polar pSer residues in their scaffold.
269 As previously shown, this was not always the case in our study and we rather observed two trends in
270 the elution order of the peptides depending on the stationary phase grafting.

271 In order to illustrate the effect of phosphate groups (pSer) on the retention of the cyclic peptides, their
272 retention factors k' were plotted against the number of pSer in the sequence. In each case, the mobile
273 phase composition was chosen to obtain k' less than 30, while keeping satisfying resolution and
274 selectivity (see Figure 4).

275 A linear correlation between the retention factor and the number of pSer was observed exclusively
276 using the neutral amide-grafted ($R^2 = 0.9489$) and Inertsil Diol-grafted ($R^2 = 0.9315$) columns. The
277 peptide hydrophilicity increases with the number of negatively charged pSer residues, inducing higher
278 retention, in agreement with classical HILIC behavior. Our results are similar to those obtained by
279 Singer *et al.*, who separated multiphosphorylated linear peptides with 0, 1, 2 and 3 phosphorylation
280 sites using a diol column, leading to increased retention in accordance with the number of
281 phosphorylation residues [27]. Furthermore, Yanagida *et al.* obtained also high correlation between
282 $\log k$ and the increasing number of hydroxy groups (-OH) in proanthocyanidins, using a TSKgel
283 Amide-80 column, and showed that it was the result of the dominance of secondary interactions
284 through hydrogen bonding on hydrophilic partitioning mechanism [35].

285 When using stationary phases involving electrostatic interactions, the peptides behave differently
286 (Figure 4). With the bare and hybrid silica columns, the retention factors increased with the number of
287 pSer residues for pS0, pS1-pS8, pS18-pS16 (group A) and then decreased for pS168 and pS1368
288 (group B).

289 All of the peptides display a global negative charge because of the presence of negatively charged
290 amino acids such as Glu (pKa = 4.07) and/or pSer (pKa₁ = 2.1 pKa₂ = 5.8), at position 1. 3. 6 and 8.
291 Their backbone is made of neutral amino acids Pro. Gly at position 4. 5. 9. 10 and Trp at position 7,
292 but the amino acid at position 2 is Arg (pKa = 12.10. charge +1) for the group A and Glu (pKa = 4.07.
293 charge -1) for the group B. This difference affects the global negative charge of the peptides, for
294 which the maximum charge at pH 7 increases as follows: pS0 (-3), pS8/1 (-4), pS18/16 (-5), pS168 (-
295 8) and pS1368 (-9). It is important to mention that the amino acids located in position 2 (Arg) and 7
296 (Trp) are orientated in the “lower face” of the peptide scaffold, contrary to the ones in position 1. 3. 6
297 and 8, that might affect their retention, since different group of different charge is available towards
298 the surface of the stationary phase.

299 Since bare and hybrid silica columns display free negatively charged deprotonated silanol groups on
300 their surface, electrostatic interactions contribute also to the retention of the peptides in addition to
301 hydrophilic partitioning. Concerning the group A peptides, additional attractive electrostatic
302 interactions taking place between the negatively charged silanol groups of the stationary phase and the
303 Arg seem to promote their retention. We can assign this behavior to the one described by Alpert as the
304 “contact region of peptides” in HILIC. being the region of these latter that preferentially interact with
305 the stationary phase [36]. Gilar and Jaworski, who studied the HILIC behavior of tryptic linear
306 peptides at pH 4.5 using bare, hybrid, and amide columns have discussed the Arg impact on the
307 peptide retention [21]. Their experiments, along with their retention prediction models, showed that
308 positively charged Arg residues strongly promoted the peptide retention on columns exhibiting
309 deprotonated negatively charged surface silanols such as bare and hybrid silica *via* cation exchange
310 interactions. This trend was more significant with bare silica compared to hybrid silica columns, due
311 to the differences in deprotonated silanol amount on the surface, which is in agreement with our
312 results [21].

313 Figure 4 shows that pS168 and pS1368 had lower retention factors compared to group A peptides.
314 These two peptides bear only negatively charged amino acids and the highest negative charge among
315 the peptides, leading to electrostatic repulsions with the stationary phase and therefore reduced
316 retention. This might explain why the retention factors of these peptides were highly affected by the
317 slightest change of mobile phase composition compared to other peptides.

318 This different behavior between group A and group B peptides is surprisingly observed with some
319 neutral columns such as YMC-Triart Diol and Acclaim-HILIC-10, but is less pronounced. This means
320 that residual deprotonated surface silanols are more accessible on these columns to interact with the
321 analytes and thus influence their retention factors despite being shielded by neutral functionalization.
322 Finally, the ZIC-pHILIC column showed similar behavior for group A peptides whilst pS168 and
323 pS1368 of group B are co-eluted. However, these latter are more retained than the first group, meaning
324 that the nature and the charge of the amino acid in position 2 did not affect the retention. The
325 secondary weak electrostatic interactions combined with the hydrophilic partitioning did not provide
326 enough selectivity to separate these two peptides. This was the case at all mobile phase compositions,
327 as seen in the previous part.

328 The HILIC behavior of the multiphosphorylated cyclic peptides differed in connection with the
329 charged amino acids (Arg and Glu) in the lower face of the peptide backbone on all the tested
330 columns, except for the amide and inertsil diol for which residual deprotonated silanols had negligible
331 effect.

332 2.4. *Impact of amino acid position on the HILIC retention of the peptides*

333 The positional isomers of mono- and di-phosphorylated peptides differ only by the location of one
334 pSer residue in the sequence, as can be seen in pS1 c(**pS**REPGEWEP**G**)/pS8 c(EREPGE**WpSPG**) and
335 pS16 c(**pS**REPG**pS**WE**PG**)/pS18 c(**pS**REPGEW**pSPG**) (Figure 1). We achieved a successful
336 separation of these positional isomers with most of the columns, leading to systematic stronger
337 retention of pS1 and pS16 compared to pS8 and pS18 respectively. This shows that the position of the
338 pSer residue significantly affect the HILIC behavior of the peptides. In the mono- and di-
339 phosphorylated peptides, the pSer residue in position 8 is neighbored by Pro and Trp amino acids,
340 while in their positional isomers it lies between Gly and Arg for pS1 and Gly and Trp for pS16 (Figure

341 1). Moreover, in pS16, both pSer residues are located close to Gly residues. We can suggest that the
342 Pro and Trp amino acids close to pSer induce higher steric hindrance in pS8 and pS18 than the amino
343 acids in their isomer counterparts, making thus the pSer residue less available to interact with the
344 stationary phase and therefore lower retention of pS8 and pS18 than pS1 and pS16.
345 The major effect of amino acid position in the peptide sequence on retention in HILIC has also been
346 reported in the literature based on prediction models and experimental investigations [21.24.28] using
347 linear peptides, where amino acid were positioned at N-terminus or at different other positions.
348 Although peptides involved in our work are cyclic and structured, we obtained results in agreement
349 with these studies.

350 Conclusion

351 The main objective of this work was to separate synthetic multiphosphorylated cyclopeptides and their
352 positional isomers at physiological pH using HILIC coupled to ESI-MS. and to shed light on their
353 retention mechanisms. By screening several stationary phases and mobile phase compositions, the best
354 separation selectivity and baseline resolution were achieved by using columns grafted with neutral
355 amide (Acquity UPLC BEH amide) and diol (YMC-Triart Diol) functional groups, with a mobile
356 phase containing 70 and 75 % ACN and 20 mmol L⁻¹ ammonium acetate, respectively (see Figure 2
357 and Figure 3A).

358 The HILIC retention mechanism study showed that peptide retention factors followed the classical
359 HILIC mechanism with the amide and Inertsil Diol-grafted columns, and a linear correlation between
360 retention factors and the number of polar phosphorylated residues was obtained. With the remaining
361 columns, we observed that the nature and charge of the amino acid at the lower face of the peptide
362 backbone affected the peptide retention, depending on the contribution part of the secondary
363 electrostatic interactions with the residual deprotonated silanols at the surface of the stationary phase.
364 The position of the amino acid in the backbone had also an impact on the peptide retention, making it
365 possible the separation of mono- and di-phosphorylated positional isomers with satisfying baseline
366 resolution. The next step of this work will focus on the separation of uranium complexes formed with
367 these peptides at physiological pH and the quantification of uranium among these peptides, using
368 HILIC coupled to elemental and molecular mass spectrometry.

369 Overall, this study gives an insight on the HILIC approaches that can be undertaken for separating
370 cyclic peptides, which can be of great concern for the separation of molecules of cyclic structure, in
371 pharmaceutical, proteomics and therapeutic applications. Furthermore, the high selectivity obtained
372 for separating isobaric phosphopeptides might be particularly useful in proteomics to help identifying
373 phosphorylation sites in proteins through the separation of peptides from protein digests.
