The main aim of this work is to assess the realistic heat loads on the first wall of the JT-60SA vessel. To achieve this scope, for the first time the entire vessel and the subdivertor region is modeled by the fluid transport code SOLEDGE-EIRENE [1]. Whereas the full scenario modeling was reported elsewhere [2] here we focus on the initial phase of scenario #2 with carbon divertor and limited heating power.

**Simulation setup** SOLEDGE-EIRENE is used in transport mode for the full current inductive scenario #2 of JT-60SA with the following setup: plasma influx at core boundary  $S_i = 1 \cdot 10^{21}$  part./s, auxiliary heating power at core boundary within the interval  $P_{aux} =$ [15, 30] MW with 2.5 MW steps, divided 50/50 between ions/electrons. Neutrals source is provided by deuterium fuelling by gas puff  $\Gamma_D = 1 \cdot 10^{21}$  part./s and recycling on carbon wall with reflection coefficient R=1 for main plasma and R = 0.1 for C ions, if present. Two main cases are considered: **STD** "standard" case with two pumping surfaces situated at the entrances of the subdivertor volume (Fig.1A) and **SUBD** "subdivertor" case which mesh incorporates also the subdivertor volume with a pump situated at the surface covering the real cryopump com-

Figure 1: The meshes used: (STD) with two pumping surfaces, (SUBD) with subdivertor structure and one pumping surface. The position of pumps is marked by red line. D fuelling valve position is marked by  $\blacktriangle$ . Outer midplane profiles of particle radial diffusion coefficient  $D_{\perp}$  and electron and ion heat radial conductivities  $\chi_e$ ,  $\chi_i$ , respectively, are presented below (OMP).

partment, see Fig. 1B. In this case the gaps between the dome and subdivertor structure are treated as semi-transparent surfaces with reflection coefficients 0.25 and 0.2 for the inner and outer gap, respectively. The albedo of each pumping surface is set to 0.95 (0.1 for C). No seeded impurities were

considered. In case of carbon its only source was sputtering described by the Bohdansky formula [3]. For all cases the transport coefficients profile depicted in Fig. 1C was used, based on previous results [4]. The profiles are expanded over the whole volume according to  $\psi$ -map.

**Outer midplane profiles** Fig. 2 presents the comparison of the electron density  $n_e$  and temperature  $T_e$ profiles at the outer midplane (OMP) for the case with  $P_{aux}$ =15MW. Only a small difference between  $n_e^{sep}$  values in the two investigated cases is visible, both reach the value of about  $3.6 \cdot 10^{21}$  m<sup>-3</sup>. For the cases with C (dashed lines) this value lowers to  $\sim 3.0 \cdot 10^{19}$  m<sup>-3</sup>. Both values are higher than the value predicted for the scenario  $\#2 \le 2.5 \cdot 10^{19} s^{-1}$  [5]. The table in the figure reports the OMP  $n_e$  decay length, resulting mainly from the assumed transport profile. The electron temperature at the separatrix is around 115eV for both geometries, regardless of C impurity presence.

Figure 2: The OMP  $n_e$  profiles for all configurations at  $P_{aux}=15$  MW (A) and the corresponding electron temperature profiles (B).

tron density in the core  $\langle n_e \rangle = 5.6 \cdot 10^{19} \text{m}^{-3}$  [5] for both STD and SUBD cases already at  $P_{aux}=20$  MW, step-wisely moving from scenario #2 to #3. It is worth noting that the Greenwald density limit  $n_{\text{GW}}=13 \cdot 10^{19} \text{m}^{-3}$  is still higher than the highest value achieved  $n_e \approx 7.8 \cdot 10^{19} \text{m}^{-3}$  for the 30MW STD case. Reason for such a big increase lies in a strong increase in the plasma sources (mainly in the inner and outer divertor volume): in terms of total values it changes linearly with  $P_{aux}$  from  $1.5 \cdot 10^{24} \text{s}^{-1}$  to  $3.6 \cdot 10^{24} \text{s}^{-1}$  for the lowest and highest  $P_{aux}$  cases, whereas this increase for the cases with C is from  $0.9 \cdot 10^{24} \text{s}^{-1}$  to  $1.5 \cdot 10^{24} \text{s}^{-1}$ . This is why the cases with C impurity are able to accommodate the large change of  $P_{aux}$  with relatively low change in  $n_e^{\text{sep}}$ : from  $\sim 3.0 \cdot 10^{19} \text{ m}^{-3}$  to  $\sim 4.2 \cdot 10^{19} \text{ m}^{-3}$ . However, it is assisted by an increase in carbon sputtering leading to an increase of carbon concentration at the OMP  $n_c^{\text{sep}}$  from  $5.5 \cdot 6.2\%$  for  $P_{aux} = 15$  MW to  $9.6 \cdot 10.3\%$  for the  $P_{aux}=30$  MW case. The average C concentration on the level of 8% was reported previously for COREDIV simulations for a similar  $n_e^{\text{sep}}$ , but for even higher  $P_{aux} \approx 35$  MW [6]. It should be noted that no outward pinch velocity was used in the simulations, it can be introduced in the future to account for impurity flushing mechanisms like ELM-s.

Additionally, in the inset of Fig. 3B the volume integrals of C radiation  $P_{RAD}^{C}$  are presented by the

specific region of tokamak chamber. One can see that the largest fraction of  $P_{RAD}^{c}$  is produced in the outer divertor volume. The inner divertor volume is about 50% less effective in terms of radiative power dissipation. There is also a non-negligible part of the radiation in the private flux region below the X-point. For the case of  $P_{aux}$ =15MW the total amount of C radiation is 3.4-3.7MW for STD and SUBD cases, respectively. D radiation losses are in both cases on the level of 0.7MW. This results in total amount of heat delivered to the divertor targets at the level of 11 MW.

Figure 3: The OMP  $n_e$  profiles for both geometries in  $P_{aux}$  scan: (A) presents the results for pure D plasma and (B) with C impurity. In this case also total C concentration profile is presented. The inset: C radiation power split into regions: CORE - confined plasma, MAIN SOL - main chamber SOL, INNER DIV/OUTER DIV - inner/outer divertor volume, PFR - private flux region.

**Conditions at the target plates** The case with  $P_{aux}=15$  MW was selected as most interesting to further investigate in detail. It can be interpreted either as a case with very limited heating power and no additional impurities or a case with a substantial energy dissipation in the core plasma by mid/high-Z impurity radiation.

Fig. 4 presents the set of parameters describing the conditions at the targets for the  $P_{aux}=15$  MW case. One can observe that the inner target exhibits lower  $T_e$  and higher  $n_e$ , a well-known experimental and modeling feature [7, 8], causing different heat load on both targets. For the outer target the peak heat load  $Q_{ToT}^{MAX}$  exceeds 10 MWm<sup>-2</sup> steady-state operational limit [5] already at this relatively low heating power for all investigated cases. This findings are in agreement with previous modeling [4] and similar conclusion follows: for safe scenario operation an additional power dissipation mechanism is required, for instance by a seeded mid-Z impurity.

For the cases with C the peak heat load on the targets is visibly lower for the SUBD case, especially for the outer target. It should be mentioned that among the investigated cases neutrals deliver at maximum ~ 2.6  $MWm^{-2}$ , which is a remarkable fraction (about 20%) of the local  $Q_{TOT}$ . For the rest of the chamber wall the highest heat load is on the corner of the dome close to the inner target. In the cases with C it receives about 0.1  $MWm^{-2}$ . This is well below the operational limit for this element (1.0 MWm<sup>-2</sup> specified in JT-60SA Plant Inte-

gration Document). Even for the highest  $P_{aux}$  case its heat load never exceeds 0.5 MWm<sup>-2</sup>. The last

Figure 4: Comparison of the inner and outer target profiles for the  $P_{aux}=15$  MW case: (A, B) - electron temperature, (C, D) - electron density and carbon density, (E, F) - total heat load  $Q_{TOT}$  and the contribution of neutral particles  $Q_0$ . ISP and OSP - inner and outer strike point, respectively. (G, H) - the neutral pressure in the divertor and subdivertor volume for the cases with C.

observation is that despite different neutrals distribution in the outer pump duct entrance (compare Fig.4G and H) the final results seem not to be affected by different geometry. Important is what are the conditions at the strike points, and these converge to a similar working point, regardless how the neutrals fill up the available space. However, it might have a bigger influence while modeling detachment.

**Conclusions** A power scan was performed for the fully inductive scenario #2 of JT-60SA in the range of [15,30] MW. In the pure-D case with increasing  $P_{aux}$  the  $n_e^{sep}$  increases and  $\langle n_e \rangle$  exceeds the nominal scenario value due to increase of plasma source at the targets. In the cases with C this increase is less pronounced. For them C concentrations between 5.5% and 10.3% are observed. Even for the lowest  $P_{aux}$ =15 MW the heat load at the outer target exceeds the steady-state operational limit of 10 MWm<sup>-2</sup> indicating a need of an additional power dissipation mechanism in the SOL/pedestal. For the investigated working point the results for STD and SUBD geometries do not differ significantly (1MW corrections to radiative heat flux at higher  $P_{aux}$  in the outer target voulme).
